Cervical spine CT should be considered as a first-line imaging modality in children receiving a head CT scan for a head injury, and in children with a high clinical pretest likelihood for cervical fracture. Although the negative predictive value of plain radiographs in low-risk populations seems high, the sensitivity of plain films to detect fractures is far less impressive. When obtained, plain radiographic evaluation should routinely consist of three views: a cross-table lateral, an anteroposterior, and an open-mouth odontoid view. The sensitivity of the three-view cervical spine series is highly variable. Interpretation of plain cervical spine radiographs in children may be especially challenging because of the anatomic changes that occur with growth (see Box 38-10). In addition, pseudosubluxation of C2 on C3 is common on nonextended cervical spine radiographs in children up to adolescence, occurring in approximately 40% of patients.[42] The emergency physician distinguishes between pseudosubluxation and true subluxation on nonextended cervical spine radiographs through use of the posterior cervical line and the relationship of the spinolaminar line (also called the *line of Swischuk*) to the anterior cortical margin of the spinous process at C2. A line is drawn from the anterior cortical margin of the spinous process of C1 down through the anterior cortical margin of C3. If this line at C2 crosses the anterior cortical margin of the spinous process at C2 or is anterior to it by less than 2 mm, no anterior cervical soft tissue swelling is seen, and no fractures are visualized, the patient likely has pseudosubluxation versus true subluxation at that level (Fig. 38-2). Pseudosubluxation may be seen less commonly at C3-C4 as well. Exceptions to this guideline do occur, and the clinical scenario is taken into account before it is applied.

www.ketabpezeshki.com 66485457-66963820

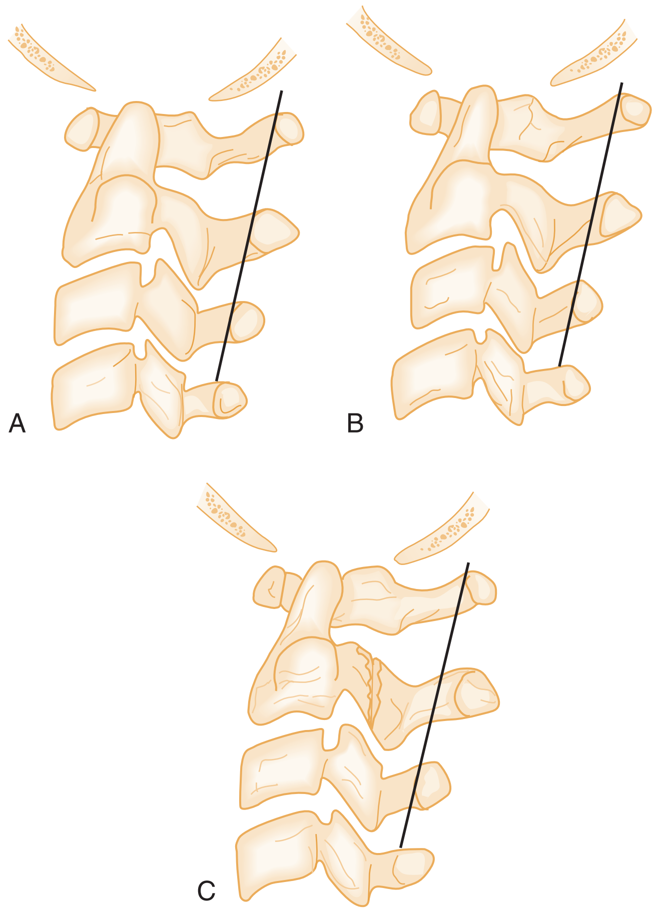

Figure 38-2. Spinolaminar line. Use only to access anterior displacement of C2 on C3. A line is drawn from the cortex of the spinous process of C1 to the cortex of the spinous process of C3, and the relationship of the spinous process of C2 is noted. **A,** Normal line passing through the cortex of C2. **B,** Normal line passing within 1.5 mm of the cortex of C2. **C,** Abnormal line passing more than 2 mm anterior to the cortex of C2, suggesting underlying fracture of posterior elements of C2. (From American Academy of Pediatrics and American College of Emergency Physicians: APLS: The Pediatric Emergency Medicine Resource, 4th ed. Sudbury, Mass, Jones and Bartlett Publishers, 2004.)

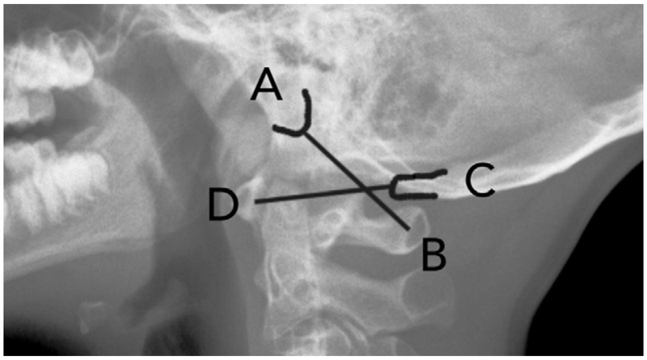

Figure 38-3. Power's ratio is calculated as the ratio of the distance from the basion *(C)* to the anterior cortex of the posterior arch of the atlas *(D)* divided by the distance from the opisthion *(B)* to the posterior cortex of the anterior arch of the atlas *(A)*. A ratio of greater than 1 indicates an atlanto-occipital dislocation. The figure shows a normal Power's ratio.

An important criterion for radiographic clearing of the cervical spine is complete visualization of all seven cervical vertebral bodies on plain film down to and including the C7-T1 interface. The predental space should be less than 6 mm in children younger than 6 years, and the prevertebral soft tissue space should not be greater than normal (variable but generally one third to one half the vertebral body width). The four cervical radiographic lines should be evaluated, and the atlanto-occipital alignment should be assessed for dislocation in this region. If there is any question of injury, thin-section CT and MRI can be used to delineate injury. If the dens cannot be adequately assessed by the open-mouth odontoid view, then a transforaminal view or CT scan should be used. Patients with high clinical suspicion for fracture but negative plain radiographs should be considered candidates for computed tomographic evaluation and radiologic, orthopedic, or neurosurgical consultation.

The pretest likelihood of fracture is considered when decisions are being made regarding the removal of cervical immobilization in children with apparently normal imaging. Patients with continued neck pain despite negative radiographs or CT may require MRI evaluation.[45] Rare cases may necessitate evaluation by neurosurgery under fluoroscopy. The use of flexion-extension views is rarely indicated or helpful.

Classically, young children have been considered at greater risk for upper cervical spine injury. Unfortunately, many occipital cervical junction injuries are immediately fatal. However, survival is possible in some cases.[46] Early detection and immobilization is crucial. Occipital cervical junction injuries should be suspected in any child pedestrian versus vehicle accident, especially if the child has a laceration under the chin from a forward fall. In many fatal cases, distraction and displacement are obvious. However, in nonfatal cases, they can be subtle. A Power's ratio greater than 1 indicates an atlanto-occipital dislocation until proven otherwise (normal, approximately 0.77). Power's ratio is shown in Figure 38-3. It is calculated as the ratio of the distance from the basion to the anterior cortex of the posterior arch of the atlas divided by the distance from the opisthion to the posterior cortex of the anterior arch of the atlas. An additional method to suggest this injury is to draw a vertical line from the posterior border of the odontoid and then measure the distance from this line to the basion. If this distance is greater than 12 mm, then atlanto-occipital separation should be suspected.

A traumatic or even sometimes nontraumatic atlantoaxial rotatory subluxation should be suspected in a child with a fixed rotatory cervical abnormality. Classically, this can be differentiated from a muscular torticollis in nontraumatic cases by the history, the time course, and the presence of palpable spasm of the sternocleidomastoid muscle on the side contralateral to the direction in which the chin is pointing in the case of torticollis. When atlantoaxial rotatory subluxation cannot be confidently ruled out clinically, plain radiographs or CT should be used.

In children with upper cervical spine tenderness, it is prudent to consider a fracture of the synchondrosis between the odontoid and C2. This can be difficult to diagnose on plain radiographs, but it is often recognized as a subtle anterior tilt to the odontoid on C2. A CT scan with sagittal reconstructions will clarify this entity and in many cases should be considered as a first-line imaging modality.[47,48]

Management

There are two phases of SCI. Direct injury (initial phase) results in largely irreversible injury to the spinal cord. Indirect injury results from preventable or reversible injury to the spinal cord secondary to ischemia, hypoxemia, and tissue toxicity.

www.ketabpezeshki.com 66485457-66963820

Resuscitation of a patient with injury to the cervical spine should focus on prevention or minimization of the indirect causes of injury to the cervical spine. Management of possible spinal cord or column injury should begin in the out-of-hospital phase of emergency care. Most injured children arrive at the emergency department with adequate immobilization. Some more recent evaluations of traditional cervical collars and rigid backboards have shown less than adequate neutral positioning of pediatric patients related to their relatively large cranium in proportion to the rest of their body. Nevertheless, in the absence of modified backboards with cutouts for the occiput of the child, the child should be immobilized with a stiff cervical collar, a rigid backboard, and external fixation by means of head blocks, cloth tape, or straps to provide adequate precautions. Appropriate padding should be placed under the shoulder blades of the patient to approximate neutral alignment of the cervical spine and help prevent pressure-related injury. Some emergency medical service agencies' protocols call for small children to be immobilized in their car seats in some circumstances.

Breathing should be assessed to determine the presence of hypoventilation. Patients with SCI may hypoventilate because of diminished diaphragmatic activity or intercostal muscle paralysis. Head or chest injury or pulmonary compromise related to contusion, aspiration, or other causes may also contribute to ventilatory embarrassment. Supplemental oxygen should be given routinely, and ventilatory assistance by BMV ventilation or definitive airway management should be considered in the presence of clinically significant hypoventilation. Finally, circulatory status is assessed early in the trauma patient and needs to be addressed promptly to prevent end-organ perfusion deficits. Hypotension can result from hypovolemia, neurogenic shock, spinal shock, or other, less common causes. Spinal shock usually results from injury above the level of T1. It manifests with lower extremity findings of SCI, with flaccid paralysis of skeletal and smooth muscle leading to the appearance of a relative hypovolemia caused by diminished systemic vascular resistance. Spinal shock generally resolves in hours to approximately 1 day once some spinal level reflexes return below the site of injury. Neurogenic shock typically occurs after injury to the spinal cord above the level of approximately T6. Patients with neurogenic shock lose their sympathetic tone and demonstrate hypotension in the face of unopposed parasympathetic action such as bradycardia. In each case, fluid administration, parasympathetic receptor blocking agents, such as atropine or glycopyrrolate, and vasopressors with chronotropic, vasoactive, and inotropic characteristics (e.g., dopamine), are used. If spinal shock with normal chronotropy and inotropy is found, then fluids and agents with more peripheral vascular vasoconstrictive properties may be preferable, such as phenylephrine or norepinephrine. Spinal shock remains a diagnosis of exclusion, once hemorrhagic shock has been definitively eliminated.

Any patient with definite SCI requires added precautions to ensure appropriate immobilization of the cervical spine. Immediate evaluation by a spinal cord specialist should be sought for all children with SCI. In the absence of such a specialist, the patient should be transported to a center with adequate facilities to care for spinal cord–injured patients.

Even when thoracic or lumbar fractures exist, patients should be expeditiously removed from the backboard to prevent discomfort and morbidity. Sliding boards (smooth movers) can be used to move patients onto scanner tables and back to their trauma beds. Mandatory inter-hospital transfer rules that require patients to remain on backboards during transport should be discouraged. The physician who initially receives the patient should be able to determine the necessity of the backboard for cervical spine immobilization during transport and, when appropriate, remove the patient from the board before transport.

Cardiothoracic Injury

Perspective

Most serious chest injuries in children (>80%) are caused by blunt trauma and result from MVCs, pedestrian accidents, and falls.[49] Isolated chest injury is a relatively infrequent occurrence considering the typical mechanisms of blunt trauma in the pediatric patient. Pediatric trauma patients with thoracic injury have a twentyfold increase in mortality over pediatric trauma patients without thoracic trauma.[49,50] Sequelae of blunt injury include rib fractures, pulmonary contusion, pneumothorax, hemothorax, myocardial injury, pericardial injury, and vascular injury.

Children subjected to penetrating trauma, in contrast to the injuries associated with blunt trauma, often die from the primary insult. Penetrating trauma accounts for 5 to 15% of thoracic insults in children.[49] Nationwide misuse of firearms has resulted in an increasing incidence of penetrating trauma, often with children as victims. The vast majority of these cases are related to the criminal use of handguns; however, improper storage and poor parental supervision lead to devastating consequences in a relatively small, but nevertheless preventable, number of cases each year. Families of children with emotional difficulties or depression should consider removing guns from their homes because of their lethality when used as instruments of suicide. All patients with self-inflicted penetrating trauma should also be assessed for ingested toxins.

Specific clinical patterns should alert the clinician to the potential for concurrent abdominal and thoracic injury. Any patient with penetrating trauma at or below the level of the nipples falls into this category.[51] Apparent isolated thoracic trauma does not exclude abdominal injury.

Principles of Disease

It is important to understand the physiology of pediatric respiration in considering the potential for early decompensation after chest injury. Infants and young children are preferential diaphragm breathers, and any impairment of diaphragmatic mobility compromises ventilation. The presence of gastric distention elevates the diaphragm and severely diminishes the vital capacity of a child. In addition, the particular types of muscle fibers involved in the diaphragm of infants and young children predispose them to the sudden development of apnea when these muscles become fatigued. Unlike adults, whose thoracic wall musculature can pull the ribs up anteriorly to give a larger circumference to the chest wall, children's chest wall circumference does not change drastically during respiration because a child's chest is barrel-like throughout the respiratory cycle. This also decreases the ability of children to increase their vital capacity. For these reasons, children will increase ventilation typically by increasing their respiratory rate. Most important, the presence of adequate oxygenation in a pediatric patient does not always ensure sufficiency of ventilation; confirmatory auscultatory and other physical findings are essential. End-tidal CO_2 capnography can be very useful in this regard in both the intubated and the nonintubated trauma patient.

Infants and children are anatomically protected against blunt thoracic cage trauma because of the compliance of the rib cage. Compressibility of the rib cage dissipates the force of impact, which lessens the likelihood of bony injury. This protective mechanism also may mask fairly complex pediatric thoracic insults. The compliance of the rib cage allows significant injury to occur with little apparent external signs of trauma. Multiple rib fractures are a marker of serious injury in children, with child abuse being the most likely cause, especially when fractures are posterior and in various stages of healing. In addition, the pediatric mediastinum

www.ketabpezeshki.com 66485457-66963820

is mobile, which favors the development of rapid ventilatory and circulatory collapse in the presence of a tension pneumothorax.

Specific Disorders

Pneumothorax. The development of a traumatic pneumothorax is commonly associated with significant pulmonary injury. In contrast to spontaneous pneumothoraces, these insults do not resolve spontaneously and often are associated with the presence of a hemothorax. Signs and symptoms include external evidence of chest trauma, such as abrasion, contusion, or ecchymoses; tachypnea; respiratory distress; hypoxemia; and chest pain. Decreased breath sounds may not be appreciated in children with pneumothoraces because of the wide transmission of breath sounds in the chest and upper abdomen. It is critical to listen to the chest from the axilla in children. This location helps with lateralization to distinguish decreased breath sounds on one side compared with the other and, after intubation, to assess for proper ETT position.

Management of a hemopneumothorax includes the placement of a large-caliber chest tube far enough posteriorly, near the mid-axillary line, to prevent encroaching on more anterior soft tissue that will later become part of the breast. Chest tube size for hemopneumothorax management can be found in Box 38-2 or can be found on a length-based resuscitation tape. A chest tube should be considered for any patient with a pneumothorax who will be undergoing mechanical ventilation. In the most conservative of scenarios, such as small (<20%) simple pneumothoraces without tension in a child who will not be mechanically ventilated, the child may be observed carefully for extended periods with 100% oxygen supplementation for nitrogen washout. Reassessment can be accomplished by repeat chest radiographs at selected intervals, or a pigtail catheter can be placed percutaneously with a modified Seldinger technique.

Open Pneumothorax. An open pneumothorax exists when the chest wall is injured sufficiently to allow bidirectional flow of air through the wound. The patient is unable to expand the lung because of equalization of pressures between the atmosphere and the chest cavity. Ventilation and oxygenation are severely impaired.

Management of an open pneumothorax is dictated by the size of the defect and the amount of respiratory compromise. A simple, small, open pneumothorax in a breathing patient may be treated by covering the chest wall defect with occlusive dressing, such as sterile petroleum gauze, and performing a separate incision for a thoracostomy tube. As in all cases, patients with defects that are too large to seal adequately or patients who are severely impaired with regard to ventilation are candidates for intubation.

In the out-of-hospital setting, a bandage applied over an open pneumothorax wound and taped on three sides as a temporizing measure may allow air to escape during expiration but not to enter during inspiration.

Tension Pneumothorax. Pulmonary air leaks that occur in a one-way valve arrangement favor the development of a tension pneumothorax. Increasing amounts of free air within the pleural cavity cause the mediastinal structures to shift toward the opposite side, compromising cardiac output. The final common pathway involves hypoxia, hypotension, and refractory shock. Most patients with tension pneumothoraces have severe respiratory distress, decreased breath sounds (often bilaterally), and a shift in the point of maximal cardiac impulse. In the worst scenario, there is mediastinal shift, contralateral tracheal deviation, and distention of the neck veins with decreased venous return to the thorax. In pediatric patients, signs of tension pneumothorax are often subtle. A short neck and increased soft tissue may make detection of tracheal deviation difficult. Pediatric patients with tension pneumothorax may have only subtle signs or only tachycardia, shock, and respiratory distress. The emergency physician should consider the diagnosis of tension pneumothorax and, if it is detected or strongly suspected, should treat the patient immediately with decompression. Respiratory embarrassment, hypotension, and circulatory collapse will occur without adequate decompression.

In the out-of-hospital setting, treatment includes needle thoracostomy placed in the second intercostal space in the midclavicular line or possibly in the fourth intercostal space just above the rib and anterior to the mid-axillary line. The needle should be placed above the rib margin to avoid injuring the intercostal vessels. In the emergency department, definitive treatment involves the use of a large-caliber thoracostomy tube that favors drainage of the tension pneumothorax and any accompanying hemothorax.

Hemothorax. Significant bleeding may occur when injury is directed toward the intercostal vessels, internal mammary vessels, or lung parenchyma. Without an upright chest radiograph, it is difficult to quantify the degree of bleeding on plain films. The only sign of hemothorax on a supine radiograph may be a slightly less radiolucent appearance on the affected side of the chest. Development of a massive hemothorax is rare in children and is associated most often with severe impact, such as that seen in high-velocity MVCs, falls from extreme heights, or the use of high-powered firearms. These injuries are evaluated and treated quickly. Clinically, patients have decreased breath sounds and dullness to percussion on the affected side. A pneumothorax may coexist with a hemothorax. The pediatric patient may demonstrate early or late signs of hypovolemic shock.

Any alteration in cardiovascular sufficiency should be treated with rapid fluid replacement with isotonic crystalloid solutions. The clinician should also prepare for transfusion with the institution of red blood cell replacement as necessary. Patients with profound shock may receive either type-specific or O-negative blood; crossmatched blood may be used for more stable patients. The amount of blood that is salvaged from the chest tube should be quantified to help determine the need for red blood cell replacement. Many centers have the capability to salvage blood from hemothoraces and to reinfuse it through use of an autotransfuser. As in all cases of trauma, initial measurement of the hemoglobin is often unreliable and typically underestimates the amount of blood loss caused by inadequate time for equilibration.

The treatment of hemothorax includes a tube thoracostomy. The tube needs to be large enough to occupy most of the intercostal space and should be placed laterally and directed posteriorly. In the supine patient with simple pneumothorax, chest tubes are directed superiorly; in hemopneumothorax, they are directed posteromedially. As in all interventions, repeat chest radiographs should be obtained to confirm tube position and document improvement in lung expansion. The emergency physician is often able to stabilize the patient with red blood cell replacement until surgical intervention is achieved.

Indications for thoracotomy in an operating room include evacuated blood volumes exceeding 15 mL of blood per kilogram immediately after the placement of the chest tube, persistent blood loss (e.g., exceeding 2-4 mL/kg/hr over 3 hours), or continued air leak. Emergency department thoracotomy is reserved for patients with thoracic trauma who deteriorate to cardiopulmonary failure despite maximal resuscitation in the out-of-hospital setting or emergency department. Guidelines for emergency pediatric thoracotomy are often institution specific. There are few published data on pediatric emergency department thoracotomy, and guidelines are often based on adult data. For both children and adults, more liberal use in penetrating injury and limited use in blunt trauma are recommended. In patients with penetrating chest trauma and CPR for less than 15 minutes, a left anterior thoracotomy may be warranted, whereas patients with blunt trauma should undergo rapid assessment by ultrasound for tamponade.

www.ketabpezeshki.com 66485457-66963820

If tamponade is present and CPR has been performed for less than 10 minutes, then a left anterior thoracotomy may be indicated.[52] Suggested contraindications to emergency department resuscitative thoracotomy after out-of-hospital CPR include (1) blunt trauma with CPR for longer than 10 minutes with asystole and no signs of life on presentation without ultrasound evidence of cardiac tamponade and (2) penetrating trauma with CPR for greater than 15 minutes and asystole with no signs of life on arrival without ultrasound evidence of cardiac tamponade.

Pulmonary Contusion. Penetrating and blunt thoracic trauma may result in the development of a pulmonary contusion. The compliance of the rib cage in children renders them susceptible to the development of pulmonary contusion even in the absence of external signs of chest trauma. Injury to capillary membranes allows blood to collect within the interstitial spaces, resulting in hypoxia and respiratory distress. If bleeding is severe enough, oxygenation and ventilation are impaired. Initial chest radiographs may not show the classic findings of pulmonary consolidation. In addition, in the early stages of injury, blood gases may be normal.

Treatment of pulmonary contusions includes a careful evaluation for the presence of additional injuries because significant force is necessary to cause the contusions. Most patients may be treated with supplemental oxygen and close monitoring. Most pulmonary contusions resolve without sequelae. Rare cases are associated with the development of acute respiratory distress syndrome.

Traumatic Diaphragmatic Hernia. Children involved in MVCs who are wearing lap belts are predisposed to the development of diaphragmatic herniation.[50,53] Mechanisms of injury involve sudden increases in intra-abdominal pressure. Patients initially are in stable condition, with the degree of respiratory distress directly proportional to the amount of abdominal contents that protrude into the pulmonary space. The presence of bruising from lap belt–only compression should alert the clinician to the possibility of diaphragmatic hernia and other intra-abdominal injuries (small bowel injury) and the possibility of associated thoracolumbar spinal insults such as Chance fractures. Most commonly, the herniation occurs on the left side because the liver prevents herniation of bowel on the right.[53]

Initial management for these patients involves placement of an NG tube to decompress the stomach. In cases of severe respiratory distress, intubation is indicated. BMV ventilation is avoided whenever possible. Surgery is required for repair of the injury.

Cardiac and Vascular Injuries. Injuries to the heart and large vessels are uncommon in children.[54] In cardiac and vascular injuries, an electrocardiogram may show tachycardia with low voltage (pericardial tamponade), findings consistent with acute myocardial injury (ST segment elevation), or a variety of other nonspecific abnormalities.

The most common traumatic cardiovascular injury sustained by children is myocardial contusion. Patients often have chest wall tenderness or may report generalized chest pain. Tachycardia is the most common finding. Echocardiogram may be diagnostic. Patients with myocardial contusions should be monitored closely for the development of dysrhythmias and impaired myocardial function; however, in most cases of myocardial contusion, there are no long-term sequelae.

The most life-threatening scenario involving the cardiac structures is the development of cardiac tamponade. Penetrating wounds with myocardial penetration and tamponade are potentially survivable if recognized immediately. Extravasated blood fills the pericardial space and impairs cardiac filling during diastole. Clinically, patients demonstrate tachycardia, distant heart sounds, narrow pulse pressure, jugular venous distention, and pulsus paradoxus. In the scenario of profound hypovolemia, venous distention is absent. The final common pathway involves the development of pulseless electrical activity. Ultrasound can characterize cardiac tamponade in seconds and guide therapy.

Bedside ultrasound or echocardiography defines the degree of pericardial effusion present and the significance of any diastolic dysfunction present. A simple single subxyphoid view provides the emergency physician with an excellent view of the pericardial sac and heart. Pericardiocentesis may be attempted, as treatment involves drainage of the fluid from the pericardial sac. However, significant hemodynamic compromise from an acute traumatic pericardial effusion is rarely adequately addressed with a needle pericardiocentesis owing to the amount of cardiac bleeding and subpericardial clot. Performance of a thoracotomy or pericardial window is often necessary to evacuate the pericardium adequately.

Commotio Cordis. Commotio cordis is a disorder described in pediatric patients that results from sudden impact to the anterior chest wall (e.g., when a child is struck in the chest with a thrown or hit baseball), which causes cessation of normal cardiac function. The patient may have an immediate dysrhythmia or ventricular fibrillation that is refractory to resuscitation efforts. Significant morbidity and mortality are associated with this disorder, and although most patients recover completely, some require extended treatment with antiarrhythmic agents, cardiac pacemaker placement, inotropic agents, or intra-aortic balloon pump. In patients with prolonged cardiac instability, cardiogenic shock and death are common despite maximal therapeutic intervention.

Abdominal Injury

Perspective

Serious abdominal injury accounts for approximately 8% of admissions to pediatric trauma centers. Abdominal trauma is the third leading cause of traumatic death in children after head and thoracic injuries. Abdominal trauma is the most common cause of unrecognized fatal injury in children. Pediatric abdominal trauma results from blunt causes in the vast majority of cases.

Blunt trauma related to MVCs causes more than 50% of abdominal injuries in children and is the most lethal. "Lap belt" injury, including small bowel injury and Chance fractures, may occur in restrained children involved in MVCs.[55-57] Another common cause of abdominal injury involves bicycle crashes. Handlebars are a serious cause of injury and subsequent hospitalization for the pediatric population. Often the effects of bicycle injuries may not be seen on initial presentation, with the mean elapsed time to onset of symptoms being nearly 24 hours after injury. All children with epigastric pain after blunt trauma, especially when concentrated force has been applied in this area, should be considered to have duodenal hematoma until proven otherwise. Pancreatic injury, including transection, should be strongly considered as well.

Sports-related injuries are another common cause of pediatric abdominal trauma. Sports-related injuries are associated most commonly with isolated organ injury as a result of a blow to the abdomen. At particular risk are the spleen, kidney, and intestinal tract in children. Finally, abdominal injury is second only to head injury as a cause of death in child abuse cases. All abuse victims should be screened carefully for abdominal trauma.

Principles of Disease

The anatomy of the child lends special protection from some abdominal injury patterns and predisposes the child to other types of injuries in blunt and penetrating abdominal trauma. Children have proportionally larger solid organs, less subcutaneous fat, and less protective abdominal musculature than adults. Therefore they

www.ketabpezeshki.com 66485457-66963820

have relatively more solid-organ injury from blunt and penetrating mechanisms. Children have relatively larger kidneys with fetal lobulations that predispose them to renal injury. Children also have a fairly flexible cartilaginous rib cage that allows for significant excursion of the lower chest wall, permitting compression of the internal organs. The combination of these factors provides the basis for the differences in abdominal injury patterns seen between children and adults.

Clinical Features

Pediatric patients with multiple injuries often have blunt abdominal injury. In children, history is often limited, traditional signs of decompensation seen in adults are often not as evident, and physical examination can be difficult. Subtle, early abdominal findings may be overlooked, leading to significant morbidity and mortality. The history and examination of young children who have sustained trauma is challenging because it may be difficult to know if the child hurts "all over" or has focal findings. The emergency physician may use distraction with toys, lights, bubbles, or keys to get the child's mind off the examiner and onto the distraction; in this way, areas of tenderness may be located.

Signs and symptoms of abdominal injury in children include tachypnea from impaired diaphragmatic excursion, abdominal tenderness, ecchymoses, and signs of shock. Restrained children involved in MVCs with abdominal bruising are much more likely to have an intra-abdominal injury than those without bruising.[57] Abdominal distention is a common nonspecific finding that is often the result of air swallowing subsequent to a painful event. Children with hepatic and splenic injuries may have trouble localizing their pain. Kehr's sign (left shoulder pain with spleen injury) may be the only indication of an intra-abdominal injury. Any abdominal tenderness on examination should prompt further evaluation of the abdomen. Vomiting can be associated with duodenal hematoma or traumatic pancreatic injury but is usually a late sign. Signs of small bowel injury may be delayed and noted clinically only with serial examinations. Pelvic bone stability should be assessed in cases of abdominal trauma, and a genital examination searching for signs of injury should be performed. Rectal examination is insensitive and nonspecific when used as a general screening test for all patients after serious trauma. Patients with suspected injury should receive further evaluation even if rectal examination findings are unremarkable.

Even minor falls can result in significant splenic injury. Repeated examination, prolonged observation, and close attention to vital signs are warranted for children who have sustained a direct blow to the abdomen. Any child with clinically suspicious abdominal examination findings or significant direct trauma should be evaluated further with additional radiologic and laboratory studies and/or admission for serial examination.

Diagnostic Strategies and Management

In patients with suspected abdominal injury or with mechanisms of possible injury, management and resuscitation must be rapid. Because of fear and pain, children can compound the difficulties in the management of serious penetrating or blunt abdominal trauma. Children tend to distend the stomach greatly with ingested air, which can decrease the diaphragmatic excursion. This can compromise respiratory efforts, and early decompression with an NG or OG tube should be considered. In children who have undergone major trauma and have a stable pelvis without risk of urethral trauma, a urinary catheter should be considered for decompression of the bladder, evaluation for the presence of urinary retention, examination for the presence of blood in the urine, and measurement of urine output. The bladder should be decompressed before any invasive evaluation of the abdomen to prevent accidental laceration during the procedure. Urinary catheter size estimates are shown in Box 38-2.

Box 38-11 Indications for Laparotomy

- Hemodynamic instability despite aggressive resuscitation and appropriate emergency department procedures (e.g., a decompression hemothorax or tension pneumothorax)
- Hemodynamic instability and evidence of intraperitoneal free fluid on bedside ultrasound examination (focused assessment with sonography in trauma [FAST])
- Transfusion of ≥50% of total blood volume because of massive intraperitoneal bleeding
- Radiographic evidence of pneumoperitoneum, intraperitoneal bladder rupture, grade V renovascular injury
- Gunshot wound to the abdomen
- Evisceration of intraperitoneal or stomach contents
- Signs of peritonitis

The diagnostic test of choice to assess intra-abdominal injury in stable trauma patients is rapid abdominal CT. The FAST examination can be a useful adjunct that is often readily available bedside. The finding of intraperitoneal hemorrhage alone is not necessarily an indication for surgery in a stable pediatric patient, but when the FAST is positive, it will clarify the need for abdominal CT, close observation, and possible repeat ultrasound examinations. In hemodynamically unstable children, FAST may point to the abdomen as the primary area in need of hemorrhage control and may expedite the decision to operate.

Indications for laparotomy are listed in Box 38-11. Whatever the surgical preference within a health care facility, it is important to establish a protocol for approaching these challenging patients. Patients who remain hypotensive after adequate crystalloid infusion, have active arterial bleeding on CT scan, or have consistent decreases in their hemoglobin level are likely candidates for early invasive intervention. Exploratory laparoscopy or laparotomy is often required, but patients with a known source of bleeding may be appropriate candidates for arterial embolization in an angiography suite.

Spleen Injury. Injuries to the spleen are the most common injuries in pediatric abdominal trauma. Children with injuries from MVCs, sudden deceleration injuries, and contact sports–related injuries may sustain splenic trauma. Typical findings include left upper quadrant abdominal pain radiating to the left shoulder. The abdominal examination may show evidence of peritoneal irritation in the left upper quadrant of the abdomen. Patients may be hemodynamically stable or, after significant splenic rupture or laceration, may be persistently hypotensive or in fulminant cardiovascular collapse. Stable patients may undergo CT for radiologic evaluation. Most often with minor splenic trauma, bleeding is controlled spontaneously without operative intervention; however, all patients with a splenic injury should be evaluated by a surgeon. In patients with a contained splenic subcapsular hematoma, extracapsular bleeding may occur days after capsular rupture. Patients with splenic injury should be admitted to the hospital for close observation and repeated examinations. Because of the desire for splenic salvage to maintain immunocompetency, an injured spleen is often left in place as long as the patient can be resuscitated adequately with crystalloid and blood products.

Liver Injury. The liver is the second most commonly injured solid organ in the pediatric patient with abdominal trauma. However, it is the most common cause of lethal hemorrhage, with a mortality of 10 to 20% in severe liver injury. Mechanisms of injury causing splenic injury also may cause liver trauma. Tenderness on palpation of the right upper quadrant of the abdomen and the complaint of abdominal pain in this region or in the right shoulder are signs of possible liver injury. Patients managed

www.ketabpezeshki.com 66485457-66963820

conservatively often do well; however, patients who are initially treated conservatively but then go on to require delayed laparotomy often have significant morbidity and mortality. Close observation in the hospital, serial abdominal examinations, and serial hemoglobin measurements are recommended.

Renal Injury. The kidney is less susceptible to trauma from forces applied to the anterior abdomen, but it is often injured in the pediatric patient with multiple injuries.[58] Because this organ is retroperitoneal, signs and symptoms of kidney injury are often less obvious and more diffuse than signs and symptoms of other abdominal organ injuries. Often, dull back pain, ecchymosis in the costovertebral region, and hematuria are the only clues to renal injury.[59] Renal ultrasound and CT may be used in a stable patient to assess the degree of renal involvement. Other organs, such as the pancreas and gastrointestinal tract, are less frequently injured in pediatric patients.

Penetrating Injury. Penetrating wounds to the abdomen usually require rapid evaluation by a surgeon and, in some cases, operative intervention. With hemodynamic instability, or peritonitis, urgent laparotomy is indicated. In the hemodynamically stable patient, further workup with a CT scan, local wound exploration, diagnostic laparoscopy, and observation may be warranted.

Diagnostic peritoneal tap (DPT) and diagnostic peritoneal lavage (DPL) have been largely supplanted by other diagnostic modalities in modern practice, such as CT and diagnostic laparoscopy.[60] However, they may be necessary in resource-poor areas and in large-scale disasters. The aspiration of 10 mL of blood or fecal or vegetable matter from the abdomen with DPT would typically indicate intraperitoneal hemorrhage, bowel injury, or both, and the likely need for laparotomy. DPL is performed by placing 15 mL of warm sodium chloride per kilogram in the peritoneal space and then removing the fluid by gravity. In blunt trauma, a positive DPL is defined as a finding of more than 100,000 red blood cells per milliliter, more than 500 white blood cells per milliliter, or gram-negative bacteria or vegetative material (stool) seen on microscopy. DPL does not evaluate for retroperitoneal bleeding. The threshold values must be lowered for penetrating trauma. In general, DPLs are not performed on stable patients because CT scanning can be done quickly and give the clinician far more information, especially about intraparenchymal injury and retroperitoneal injury.

Radiology. Pediatric patients frequently sustain injury to the spleen, liver, kidneys, and gastrointestinal tract. CT of the abdomen can provide high sensitivity and specificity for identification of these injuries while being relatively noninvasive.[61,62] Abdominal CT has a high negative predictive value.[61,62] Oral contrast does not add to the accuracy of CT for trauma; thus one can avoid oral contrast–related delays in evaluation, difficulty with administration, and risk of aspiration.

Another useful procedure in an acutely traumatized pediatric patient is the FAST examination. When used by an experienced clinician, ultrasonography can provide sensitive information about intraperitoneal hemorrhage without invasive measures.

Although radiologic evaluation can provide important diagnostic information in a pediatric patient with possible abdominal trauma, any patient with unstable vital signs from an obvious surgically correctable cause should receive immediate operative intervention and not be subjected to delay while radiographic screening studies are obtained. Children with persistent or recurrent hypotension, continued abdominal pain, or persistent abdominal distention should undergo expedient evaluation by a surgeon.

DISPOSITION

A key decision for the emergency physician is whether to admit a pediatric trauma patient or transfer the patient to a tertiary care facility. The decision for admission in questionable cases should be based on consultation with the surgeon and the patient's primary care physician. Infants and children who are moderately to severely injured have improved outcomes in a pediatric (specific) ICU versus an adult ICU or an adult ICU with a few segregated pediatric beds. The primary role of the emergency physician is to evaluate and stabilize the patient before admission to a pediatric ICU or before transfer to a tertiary care facility. Before transport, it is vital that the child be maximally stabilized. This may include the involvement of general surgeons, definitive surgery, or temporizing surgery (such as packing the abdomen). The emergency physician should communicate directly with the accepting physician at the tertiary care center. In general, the emergency physician should refrain from completing extensive radiologic testing in a facility that is potentially unable to manage the injury being screened for, unless the emergency physician is confident that it will not delay the transfer to more definitive care and has discussed the plan with the receiving physician. All radiographs, documents, and results of laboratory testing should be sent with the patient. Parents should be informed of the exact location to which the child is being taken and given directions to the receiving facility. Under no circumstances should the child's likely outcome be downplayed to the patient's parents before transfer because this leads to false expectations and the assumption of poor care if the promised outcome is not achieved.

Indications for admission are many, but the main criterion is to admit patients requiring ongoing monitoring for deterioration or complications of their injuries. The threshold for admission should be very low in cases in which the health care team does not believe the child will have the social support or oversight necessary to be appropriately observed or to recover in the home environment. The family should be asked if they have transportation, a phone, and access to emergency medical services if needed. In addition, children with suspected physical injury from child abuse are admitted for their protection and for medical treatment.

Cessation of Care

Despite advances in trauma care and system improvement, some injured children will die—some in the emergency department. Cases in which death is certain or has already clearly occurred, such as with decapitation and findings of livor mortis or rigor mortis, do not present treatment dilemmas. For patients with signs of life (respirations, blood pressure, pulse, pupil reactivity, or cardiac and electrical activity), resuscitative efforts should be initiated. Bedside cardiac echo can be helpful in some cases to confirm the lack of cardiac activity in patients without a pulse who continue to have electrical activity. Patients who lose their vital signs en route to or in the resuscitation room should receive maximum resuscitative efforts, potentially including emergency thoracotomy.

A final review after each death should be performed. Signs of maltreatment, congenital abnormality not previously recognized, possible personal identifying marks in patients with an unknown identity, and points for future education and study can be gained from one last mental and visual review, as can the potential for some insight related to the cause of death. Organ donation should be offered under local and state guidelines to all families of deceased children. Often it is viewed as one way that parents can make sense of the death of their child. Knowing that their child's death helped many others to live can help parents in their healing.

Parental presence should be considered in all pediatric resuscitation cases. Assigning someone to be with the parent to explain what is happening is essential. Often the parents' presence can be useful to the resuscitative effort. Information can be obtained immediately when needed from the parents, and they witness the

www.ketabpezeshki.com 66485457-66963820

effort that goes into trauma resuscitation. Very rarely, parental presence can present a true hindrance to medical care, in which case the parent can be asked to leave or can be escorted out of the room. Parents who witness what the team does for their child during resuscitation seem to better understand the abilities and limitations of medicine. In the final analysis, most parents want to be there, and frankly, at the time of death, their presence is more important than the presence of the medical team.

KEY CONCEPTS

- Trauma is the leading cause of death in children in the United States. It accounts for more than half of all pediatric deaths and more than 8 million visits to U.S. emergency departments each year.
- Proper management of a pediatric trauma patient involves most of the components of standard adult trauma protocols. If strict attention is paid to the anatomic and physiologic differences in children, the pediatric patient should achieve better outcomes.
- Continuous monitoring and reassessment of the trauma patient is essential to recognize early signs of deterioration and to discover all injuries.
- The leading cause of traumatic shock in children is hypovolemia; management priorities include appropriate ventilation, oxygenation, and fluid resuscitation to maintain perfusion.
- The diagnostic test of choice for the evaluation of intra-abdominal injury in a stable patient is CT of the abdomen.
- Controlled hyperventilation should be performed on children with signs of impending brain herniation, and P_{CO_2} levels should be maintained at 30 to 35 mm Hg to prevent secondary brain injury from excessive hyperventilation and subsequent cerebral vasoconstriction.

Chapter 39
Geriatric Trauma

Jeremiah D. Schuur

PERSPECTIVE

Background

Traumatic injuries are important causes of morbidity and mortality in older adults, and older adults make up a growing proportion of trauma patients in emergency departments (EDs). Trauma systems and protocols that were developed in the United States over the last half-century were largely informed by advances from military medicine and primarily designed to serve younger adult patients. Although the general principles of trauma care for younger adults apply to elders, there are special considerations for the older trauma patient. This chapter highlights the epidemiology, pathophysiology, diagnosis, and management of trauma in older adults and focuses on decisions that may differ from those in younger adults.

Definition of Geriatric Trauma

There is no standard definition of "geriatric trauma"; studies include patients older than 45 to 65 years. Some studies further stratify the elderly population into those aged 65 to 80 or 85 years and the "oldest old," those older than 80 or 85 years. The literature on trauma in older adults has several limitations. Older adults are frequently excluded from clinical trials, a limitation in considering high-risk interventions such as surgery or invasive hemodynamic monitoring. Furthermore, studies conducted via trauma databases include only trauma center patients evaluated by a trauma team; the results may not be generalizable to non–trauma center ED populations.

Demographics and Epidemiology

The U.S. population is aging, and the elderly are living more active lifestyles—which explains the dramatic rise in geriatric trauma. About one in eight Americans were aged 60 or older in 1994, whereas by 2030 one in five will be.[1] In 2008, U.S. adults aged 65 and older made more than 5.8 million ED visits for injuries, accounting for 30% of all visits by older adults and almost 14% of all injury-related ED visits.[2] Older trauma patients have increased morbidity and mortality owing to the severity of injury, comorbid disease, and the independent effects of age. In similar accidents, the elderly sustain more severe injuries than younger adults, a strong predictor of mortality. In 2009, unintentional injury was the ninth leading cause of death among those older than 65 years.[3] Older adults are more likely to have significant underlying medical conditions that limit their physiologic response to injury and increase the risk of death after trauma, especially in less severe injuries.[4,5] Age is independently predictive of morbidity and mortality even when comorbidities and Injury Severity Score (ISS) are controlled for.[6,7]

Age as a Triage Criterion

Age should be considered in determining criteria for transfer to a trauma center and for activation of trauma teams.[8] Traditional triage criteria based on mechanism and vital signs miss many elders with major injuries.[9-12] Fewer older patients are transported to trauma centers despite meeting trauma center criteria,[9,13] and elders are less likely to be admitted to trauma centers than younger adults.[14] In response, the Advanced Trauma Life Support (ATLS) program recommends that emergency medical services (EMS) transfer patients older than 55 years to a trauma center regardless of injury severity.[15] Yet the effect of trauma center care on elders is not clear; although an early study showed that elderly patients with severe injuries have better outcomes when treated at a trauma center,[16] a larger, more recent study of 69 hospitals in 14 states found no survival difference.[17] At trauma centers, age is often a criterion for trauma team activation, and one study showed a trend toward decreased mortality after trauma team activation criteria were changed to include age older than 70 years.[18]

Mechanisms of Injury

Falls are the leading mechanism of injury and the leading cause of injury-related death in patients older than 65 years.[19] In 2008, there were 2.1 million ED visits for falls among those 65 and older—10 times more common than motor vehicle collisions (MVCs).[20] Up to one third of elders sustain a significant fall each year, and serious injuries occur in up to a quarter.[21] Most falls are from standing and occur at the elder's place of residence.[19] Risk factors for falling include (in decreasing relative risk) weakness, balance or gait deficit, visual deficit, mobility limitation, cognitive impairment, impaired functional status, and postural hypotension.[22] Fractures are the most common injuries sustained by elders during falls, occurring in 5 to 10% of falls.[21] Up to 10% of fallers sustain a major injury, with head injury being most frequent.[23] Although the height of the fall is associated with severity, falls from standing carry significant risk for older adults; same-level falls result in serious injury (ISS >15) 30% of the time in older patients, and peri-injury mortality from low falls is up to 10%.[23-25]

MVCs and pedestrians struck by a motor vehicle are the second and third most frequent causes of trauma in older adults.[6,19] Elders are more likely than younger adults to be involved in daytime crashes occurring close to home.[26] A detailed crash history is important, and single-vehicle crashes should raise the suspicion

www.ketabpezeshki.com 66485457-66963820

that a medical problem caused the crash (e.g., syncope). The mortality rate of older MVC victims is up to 21%.[19,27] Elders are more likely to be struck by a motor vehicle than younger pedestrians, because of poor eyesight, limited mobility, and slower reaction time. Pedestrians struck sustain significant injury patterns and have the highest fatality rate among injuries, 30 to 55%.[19]

Self-injury, elder abuse, and thermal injuries are less common but important injury patterns in the elderly population. Older adults have a lower likelihood of attempting self-injury but a higher likelihood of completing suicide attempts than any other age group, with men at higher risk. Thermal injuries such as burns and smoke inhalation occur more frequently and are more severe in older adults owing to decreased mobility and physiologic skin changes.[28] Elder abuse is a complex problem that can involve psychologic, social (e.g., financial), and physical abuse. Studies have identified that around 5% of elders self-report abuse in the previous month, although lower rates of physical abuse are reported to protective services.[29] All older adults with injuries should be asked if they feel safe at home and if there is anyone in their life who is threatening or injuring them.

DISTINGUISHING PRINCIPLES OF DISEASE

Older adults are more vulnerable to trauma owing to age-related changes in anatomy, physiology, and pathophysiology. Aging's main effects on human physiology are decreased functional reserve, seen across organ systems, due to reductions in volume of viable tissue and intrinsic function of the tissues. Older adults are more likely to have comorbidities and to be taking multiple medications that affect their likelihood to get injured and their response to injury. Aging physiology, comorbid disease, and medications lead to different signs and symptoms of trauma in older adults and should inform the assessment of the geriatric trauma patient.

Decreased Physiologic Reserve

A primary effect of aging on human physiology is decreased functional reserve, a progressive process seen in all organ systems. Older adults are less able to compensate for physiologic demands of hypovolemia and stress resulting from hemorrhage associated with trauma. Whereas older adults in a good state of health have sufficient reserves to accomplish activities of daily living, when they are stressed by acute trauma and the subsequent response to injury, the decrease in physiologic reserve can lead to tissue hypoperfusion and organ failure, a common cause of death in older trauma patients.

Comorbidities

Older adults are likely to have significant comorbidities at the time of injury. The percentage of the elderly population experiencing at least one of five chronic diseases (arthritis, cerebrovascular accident, chronic lower respiratory tract disease, coronary heart disease, and diabetes mellitus) varies from 15 to 47%, with only 33% of men and 25% of women having none of these comorbidities.[30]

Effect of Medications

Medication use is common in older adults. A representative survey of community-dwelling U.S. adults (aged 57 through 85 years) showed that 81% used at least one prescription medication, and 29% used five or more prescription medications.[31] Aspirin was the most common medication, used by 28% of older adults. Medications increase the likelihood of older adults getting into traumatic accidents (e.g., sedative hypnotics causing falls). Some, such as beta-blockers, affect the physiologic response to trauma. Medications' effect on vital signs should be considered during the primary survey, and a full medication history should be taken early in the secondary survey.

Modifications to the Trauma Assessment of Older Adults

A systematic trauma assessment, as described in previous chapters, including a primary and secondary survey and concomitant resuscitation should be conducted in older adults. Yet many signs and symptoms of injury in the younger adult, such as hypotension, tachycardia, and pain, will be mild or absent in many older adults. Normal vital signs should not be reassuring, as significantly injured older adults often display delayed hemodynamic signs of injury.

Primary Assessment and Resuscitation

Airway

Establishing and maintaining a patent airway is the primary objective. As elderly patients are likely to have multiple risk factors for a difficult airway, physicians should perform a systematic airway assessment, focusing on the ability to mask ventilate, to perform endotracheal intubation, and to perform a cricothyrotomy. Early intubation is indicated for unstable patients as defined by signs of shock, altered mental status, and significant chest trauma.[15] As direct laryngoscopy is more difficult in older adults because of limited cervical mobility and less mobility at the temporal mandibular joint, videolaryngoscopy is recommended.[32] Cricothyrotomy is more likely to be complex in older adults as they are more likely to have had neck surgery, radiation, or tumor and are more likely to be anticoagulated.

Rapid sequence intubation (RSI) medications should be tailored to the older adult. The main risk from RSI in the older trauma patient is hypotension from medications, so dosages of induction agents should be reduced (e.g., etomidate, regular strength 0.3 mg/kg, or half strength 0.15 mg/kg; midazolam, 0.1 mg/kg in average older adults, or 0.05 mg/kg in frail elders). Older adults are more likely to have risk factors for succinylcholine-related hyperkalemia, such as recent stroke or neuromuscular disease. With a good history, succinylcholine at a regular dose (1.5 mg/kg) is safe, but in the trauma patient without clear history, it is reasonable to use a nondepolarizing neuromuscular blocker such as rocuronium (1 mg/kg).

Breathing

High-flow supplemental oxygen should be applied to all patients, including those with chronic pulmonary disease. The short-term benefits of avoiding hypoxia and increasing oxygen reserves are critical as older adults have reduced pulmonary reserve, which can lead systemic pulmonary injuries to overwhelm the ability to oxygenate and ventilate. Respiratory rate should be closely followed as older adults are more likely to tire and can rapidly decompensate as a result of pulmonary injuries or aggressive fluid resuscitation.

Circulation

Elderly patients are particularly vulnerable to shock, as their blunted response to stress and limited physiologic reserve raises the risk of organ dysfunction. Assessment of circulatory status is complicated as responses to hypovolemia, such as tachycardia and hypotension, are blunted by physiologic changes and medications, such as beta-blockers and calcium channel blockers. Vital signs are

www.ketabpezeshki.com 66485457-66963820

insensitive, as normal blood pressure does not reliably exclude significant hemorrhage or shock. As systolic hypertension is more common among elders, normotension may indicate significant hypovolemia. Vitals signs should be frequently reassessed; in elderly trauma patients, trends are more important than specific cutoffs.

First, life-threatening bleeding is identified and stopped; this includes external bleeding, such as scalp hemorrhage, which can be significant in older adults. The focused assessment with sonography in trauma (FAST) is an important adjunct to the primary survey but has not been specifically studied in elderly patients. A urinary catheter can be placed to monitor urine output, although this is a less sensitive predictor of renal blood flow than in younger patients.

Fluid resuscitation should be initiated with defined boluses (e.g., 500 mL) of warmed isotonic crystalloid. Start resuscitation with blood in the patient with significant bleeding, signs of hemodynamic instability, or significant injuries (e.g., unstable pelvic fracture), as older adults do not tolerate large-volume resuscitation well. Hemodynamic status should be reassessed frequently after small fluid boluses to avoid causing respiratory failure from fluid overload.

Invasive hemodynamic monitoring is appropriate for severely injured elders, but routine use is not justified. In a single-center, pre-post study, Scalea and colleagues showed reduced mortality with early invasive monitoring, leading some to recommend this as standard for older trauma patients.[33] Yet this has not been replicated, and multiple randomized trials of invasive monitoring in other critically ill populations have not shown a survival benefit.

Prompt reversal of anticoagulation is important, as approximately 5% of the elderly population is on warfarin and others have pathologic coagulopathy.[31] Specific considerations for reversing coagulation abnormalities in elderly trauma patients are the volume of reversal agents required and the corresponding risk of fluid overload. Prothrombin complex concentrates (PCCs) require minimal volume compared with fresh frozen plasma (FFP) but are costly. To fully reverse anticoagulation, 2 to 4 L of FFP may be required, presenting a limitation to rapid reversal in older patients at risk of fluid overload.

Disability

Evaluation of the elderly for disability includes examination for traumatic brain injury (TBI), spinal cord injury (SCI), and vertebral fractures and injuries. Primary neurologic examination of older adults should focus on mental status, verbal responsiveness, pupil responsiveness, and gross motor examination. The Glasgow Coma Scale (GCS) is often used to detect mental status changes after TBI but was not designed for this purpose and lacks sensitivity for mild injuries. Any GCS score less than 15 is concerning for TBI, and a GCS below 8 is highly predictive of poor outcome.[34,35] In addition to application of the GCS, other means of assessing mental status changes are useful. Subtle changes in mental status, such as confusion or decreased alertness, or symptoms such as headache may be the only signs of TBI. The mental status examination in elders is complicated by comorbidities such as previous stroke or dementia and the increasing prevalence of cognitive impairment in older adults, including dementia and delirium. Delirium can be the cause of traumatic injury, such as falls, or the result of traumatic injuries.[36] Abnormal pupillary responsiveness or motor function should raise concerns for significant intracranial hemorrhage (ICH) with associated increased intracranial pressure (ICP). Ultimately, no combination of historical features and physical findings has been shown to reliably predict the absence of intracranial injuries in the elderly trauma population. Brain computed tomography (CT) is prudent in older adults with head trauma, significant multisystem trauma, and symptoms or signs of TBI.

Older adults are at higher risk of vertebral fractures, and cervical fractures in particular, and they are more likely to sustain SCI as a result of trauma. Vertebral examination can be confounded by preexisting osteoarthritis. Clinical decision rules are available for cervical spine imaging in trauma, but their use is not recommended in older adults. The Canadian C-Spine Rule (CCR) classifies all patients 65 years and older as inherently "high risk," requiring radiography, as the derivation study found that age older than 65 had an odds ratio of 3.7 (95% confidence interval [CI] 2.4-5.6) for clinically significant cervical spine injury.[37] The National Emergency X-Ray Utilization Study (NEXUS) included all ages but found that patients aged 65 and older had a relative risk of 2.1 (1.8-2.6) for clinically significant cervical spine injury.[38] Although a subgroup analysis of the NEXUS study in elderly patients concluded that no clinically significant injuries were missed, there was likely selection bias, as the NEXUS study was observational and clinicians are more likely to order imaging in older adults. Other studies show that only 45% of elderly patients with cervical spine fractures had cervical spine tenderness on examination.[39] Elders are also at increased risk of thoracic, lumbar, and sacral vertebral fractures, for which CT is more sensitive than the physical examination or plain radiography.[40,41] Physicians should have a low threshold for CT imaging of the spine.

Elders are at higher risk for SCI without obvious radiographic abnormality (SCIWORA) owing to spinal cord stenosis and cervical kyphosis. Preexisting spinal canal stenosis increases the risk for central and anterior cord syndromes.[42] Evaluation for ligamentous injury and SCI with magnetic resonance imaging (MRI) is appropriate in patients with focal neurologic deficits.

Exposure

Older trauma patients are more likely to develop hypothermia because of physiologic changes and mechanisms of injury. With aging, skin thins, muscle and fat mass decrease, and thermoregulatory mechanisms do not work as well. Prolonged immobilization with exposure to the elements is common when elders fall and cannot get up. A rectal temperature should be routinely taken, and hypothermia should be rapidly treated with active external rewarming and warmed fluid resuscitation. Because skin breakdown and relatively minor wounds can cause serious complications in older patients, elders should be removed from backboards as soon as possible, be examined for pressure ulcers, and receive tetanus immunization if it is not up-to-date.

Secondary Assessment

The stable geriatric trauma patient requires a thorough secondary assessment. A complete history should be obtained from the patient or a care provider with particular emphasis on corroborating the accident history, past medical history, medications and allergies, and social history including baseline functional status and living arrangements. Screening questions for alcohol and substance abuse and elder abuse should be routinely asked. A valid screening question for elder abuse is "Has anyone close to you tried to hurt you or harm you recently?"

Laboratory Testing

Reasonable routine laboratory tests include complete blood count, comprehensive metabolic profile, coagulation studies (international normalized ratio [INR]), urinalysis, cardiac enzymes, and toxicology. Lactate and base deficit, which can signal tissue hypoxia and organ dysfunction, are predictive of mortality and can help

www.ketabpezeshki.com 66485457-66963820

determine the prognosis in elders with normal vital signs.[43] An electrocardiogram and cardiac monitoring are advised.

Imaging

Unstable elders should undergo plain radiography of the chest and pelvis. CT is the imaging modality of choice for stable older trauma patients, as plain radiography is less sensitive in elders owing to osteoarthritis and other comorbidities. Elders have less additional lifetime risk from the radiation associated with CT scans than younger adults owing to their lower life expectancy, but they are at greater risk from contrast-introduced nephropathy. When possible, intravenous contrast should be avoided, and renal protective strategies should be used, including intravenous fluids, bicarbonate, or *N*-acetylcysteine.[44]

SPECIFIC DISORDERS

Traumatic Brain Injury

TBI is common in older adults, can occur with minimal head trauma, and can be asymptomatic. Increasing age is an independent predictor of disability and mortality in patients with TBI, with overall mortality rates ranging from 30 to 80%.[34,45]

Pathophysiology and Mechanisms of Injury

Physiologic changes of aging and the frequent use of anticoagulant medication increase the likelihood and severity of TBI in older adults. With aging, the size of the brain decreases by 10% on average, resulting in less tortuous bridging veins and increased intracranial free space. The atrophied brain is more mobile within the skull, and trauma is more likely to shear bridging veins, leading to ICH. Diagnosis of TBI is more difficult in elders as increased intracranial free space can allow the accumulation of blood without changes in mental status,[46] and preexisting cognitive impairment is increasingly prevalent in older adults. Approximately 5% of older adults are on warfarin, and more than 30% are on an antiplatelet agent, increasing the likelihood and severity of TBI.[31]

Assessment and Diagnosis

If there is concern for intracranial injury, cranial CT and INR are indicated. Clinical variables alone are insufficient to reliably identify all cases of significant intracranial injury following trauma in elderly patients, and both the New Orleans Criteria (exclude age >60) and the Canadian Head CT Rule (excludes age ≥65) exclude older adults.[47,48]

Treatment

Treatment of TBI includes supportive care, rapid reversal of anticoagulation, and evaluation for decompressive surgical intervention. Supportive care aims to avoid cerebral hypoxia and hypoperfusion, which are significant predictors of adverse outcomes in patients with TBI. All patients should initially receive high-flow oxygen to maintain high oxygen saturation. Patients with hypercarbic respiratory conditions (e.g., chronic obstructive pulmonary disease [COPD]) will require an individualized determination of the appropriate oxygen saturation. Preventing cerebral hypoperfusion requires close monitoring of blood pressure, urine output, and other hemodynamic parameters, and individual patients may benefit from invasive hemodynamic monitoring. Early neurosurgical consultation is indicated to assess the need for and usefulness of surgical ICP monitoring and decompression. The current guidelines for ICP management have not been studied in older adults with TBI.[34]

Prompt reversal of anticoagulation with FFP or PCC is indicated in elders with TBI. The evidence supporting PCCs is from several studies of atraumatic ICH, which showed that immediate administration of PCC was associated with more rapid reversal and less hematoma growth than vitamin K and FFP, but not better outcomes. To date, there is not clinical evidence to support the use of platelet transfusion in elders taking antiplatelet agents.

Prognosis and Disposition

TBI in older adults is associated with significant morbidity and mortality, yet ED prognosis is not precise. Negative prognostic factors include increasing age, anticoagulation,[49-53] use of antiplatelet medications,[54] greater severity of TBI, and lower GCS. Although many patients with severe injuries, significant comorbidities, or anticoagulation may have no chance of meaningful outcome, others can return to living in the community.[55] Elderly patients with TBI should undergo prompt neurosurgical consultation. This is problematic for emergency physicians at hospitals without neurosurgical coverage, as it requires transferring patients with a grave prognosis, potentially for long distances. Patients with moderate or severe TBI, or any TBI and anticoagulation, require intensive care in which frequent neurologic checks and rapid reversal of anticoagulation can be accomplished. When an elder with TBI is being transferred, reversal of anticoagulation and prevention of hypoxia and hypotension are important early management steps.

Elderly patients with isolated head trauma, a normal cranial CT, and a normal INR are safe for discharge if they have a safe environment, a responsible care provider, and reliable follow-up. Although case reports suggest that anticoagulated patients with isolated head trauma and a normal cranial CT may be at risk of a delayed bleed, one study found that routine performance of a follow-up head CT scan at 24 hours was not necessary.[56] Such patients can be discharged to the care of a responsible provider who can observe them closely.

Vertebral Fractures and Spinal Cord Injuries

Vertebral fractures and SCIs show a bimodal distribution with one peak in young adults and a second peak in the geriatric population. Age-related changes to the vertebral bones, intervertebral disks, and spinal canal place patients at greater risk of vertebral fractures, result in a greater likelihood of SCI, and make physical examination and diagnostic imaging less accurate. Based on radiologic studies, approximately one quarter of patients older than 65 years have cervical stenosis, and 90% of men older than 50 years and 90% of women older than 60 years have evidence of degenerative changes in the cervical spine.[57] These changes have the effect of creating leverage on the spinal column when an external force is applied, such as in a fall with impact to the head, concentrating force on weakened bone, and increasing the risk of fracture and SCI. Spinal canal stenosis and the resulting spinal cord compression are clinically manifested as a myelopathy, with impairment of coordination, gait, bowel or bladder function, and motor or sensory function or both. Geriatric patients with vertebral injuries and SCIs are more likely to sustain incomplete neurologic injuries of less severity than younger patients, largely because they have lower-force injuries. In cases of suspected vertebral fracture or SCI, continued immobilization, neurosurgical consultation, and admission are indicated.[38] The majority of geriatric vertebral fractures and SCIs are represented by three types of injuries: (1) central cord syndrome, (2) cervical extension-distraction injuries ("open book" fractures), and (3) odontoid fractures.[42]

www.ketabpezeshki.com 66485457-66963820

Central Cord Syndrome

Central cord syndrome is a clinical syndrome with weakness disproportionately greater in the arms than in the legs after a hyperextension injury. The majority of cases of central cord syndrome in older adults are the result of hyperextension injuries in patients with canal stenosis and no bony fracture. Injuries associated with central cord syndrome are typically stable and require immobilization with a hard collar. Surgical decompression may be indicated. Patients with symptoms concerning for central cord syndrome and without fracture should undergo MRI.

Cervical Extension-Distraction Injury

Cervical extension-distraction injury is caused by reduced cervical range of motion as a result of degenerative spondylolysis, disk space collapse, and osteophyte formation. A hyperextension injury of the cervical spine and external signs of trauma to the forehead or face in an older adult raise suspicion for an extension-distraction injury. The patient may report that he or she is able to touch the pillow on the bed with the back of the head, which he or she was unable to do before the injury. This is a result of the fracture, which opens and lengthens the anterior column of the spine, resulting in the terminology "open book" fracture. These fractures are typically unstable and require surgical fixation.

Odontoid Fractures

Fracture of the C2 vertebral body, specifically the odontoid process, is usually the result of a fall with impact to the head, resulting in anterior or posterior displacement of the odontoid process. Although the majority of odontoid process fractures are displaced, less than 10% cause neurologic deficits. Type II odontoid fractures, at the base of the dens at its attachment to the body of C2, are the most common C-spine fracture in older trauma patients.

Thoracic Trauma

Older adults are at increased risk of rib and sternal fractures, pulmonary contusions, and their complications with low-force injuries. More than half of elderly patients admitted to hospitals with rib fractures sustained them during a fall, and a significant number occurred during low- or moderate-speed MVCs.[58] The risk of pneumonia and complications increases with the number of ribs fractured.[59] Pulmonary contusions are more frequent with minimal trauma and can cause significant morbidity and mortality in older adults. Chest CT is recommended for elderly patients with significant chest trauma, multiple rib fractures by plain film, or respiratory complications from trauma.

Patients with significant chest trauma require airway monitoring with consideration of early intubation to anticipate their clinical course, pulmonary therapy, and pain control. Pain control is of particular importance, as rib fractures will lead to splinting and atelectasis and increase the risk of pneumonia. Analgesia can be administered with intravenous opioids via patient-controlled analgesia or with an epidural analgesic. Geriatric trauma patients with severe pain from rib fractures often require hospitalization to allow adequate and safe pain management, and those with flail segments or larger numbers of rib fractures may require intensive care admissions.

Abdominal Trauma

Older adults are more likely to sustain intra-abdominal injuries and have higher mortality from such injuries. The general management principles are similar to those in younger adults, although there is less clinical evidence supporting nonoperative management (NOM) and angiographic embolization (AE) of solid organ injuries. The focus of the emergency physician is on the early diagnosis of intra-abdominal injuries, vigilant hemodynamic monitoring, and early resuscitation. The physical examination is unreliable for detecting intra-abdominal injury in older adults. The FAST examination is part of the initial evaluation and can be repeated as part of ongoing hemodynamic monitoring. Elderly patients with abdominal tenderness, significant multisystem trauma, or hemodynamic instability often require CT scanning to establish or eliminate dangerous diagnoses.

Although advanced age was initially an exclusion from NOM of solid organ injuries, there is more than a decade of evidence showing that carefully selected older adults are candidates for NOM. In several case series, approximately 80% of elders with splenic injuries were successfully managed nonoperatively, with the caveat that grade III injuries were more likely to fail NOM and all geriatric patients with grade IV or V injuries required an operation.[60,61] There are limited data on NOM of liver injuries in older adults. As AE has been used successfully in older adults,[62] angiography is a reasonable option for the elderly trauma patient with solid organ injury and a blush or extravasation on CT.

Extremities

Fractures are the most common injuries in elders with trauma. Fractures that affect mobility and the ability to live independently, such as hip fractures, are associated with significant perioperative and 1-year mortality in older adults. The most common fractures in order of frequency sustained by older adults are distal radius fractures (Colles' fractures), proximal humerus fractures, and elbow fractures, which usually occur during a fall onto an outstretched arm. Older adults with proximal humoral fractures can have remarkably few symptoms.

The most common lower extremity fractures in older adults are ankle fractures, hip and pelvic fractures, and tibial plateau fractures. Pelvic fractures can occur with relatively little force in elders and are less likely to be classified as severe; fracture patterns are similar between the elderly and younger adults, with lateral compression fractures more common than anteroposterior fractures. In older adults, both fracture types are associated with significant hemorrhage.[63] Overall pelvic fracture mortality is 9 to 30%, and up to 81% in older patients with open pelvic fractures.[63,64] Emergent treatment of pelvic fractures consists of hemodynamic monitoring, resuscitation with blood, stabilization of the fracture with wrapping or external fixation, and control of bleeding with consideration of AE to address retroperitoneal hemorrhage.

Hip fractures are common in older adults, occurring in approximately 1% of men and 2% of women per year. Whereas isolated hip fractures are not associated with significant immediate hemorrhage or mortality such as seen in pelvic fractures, they are associated with an 8 to 30% 1-year mortality.[65] Hip fractures are usually seen on plain x-ray films (sensitivity approximately 90%) and CT scans, but occult fractures are a well-described phenomenon in older adults. Patients with inability to ambulate or persistent pain after trauma require further evaluation; MRI and bone scan are useful imaging studies to delineate the pathology.[66] Elders with fractures may have better outcomes with distinct orthogeriatric services.[67,68]

END-OF-LIFE DECISIONS

Emergency physicians are faced with difficult decisions regarding prognosis, the usefulness of aggressive care, and end-of-life decisions in geriatric trauma. Elderly trauma patients have a uniformly worse prognosis than younger adults. Several factors that portend a grave prognosis from the ED include a GCS of 3, a GCS below

www.ketabpezeshki.com 66485457-66963820

8 with anticoagulation, and hemodynamic instability from internal hemorrhage with anticoagulation. Yet initial injury in the ED does not perfectly predict an individual patient's long-term prognosis,[69] and emergency physicians have not traditionally withheld aggressive trauma care, which usually includes the involvement of trauma surgeons. Emergency physicians should discuss end-of-life decisions, such as intubation, cardiopulmonary resuscitation (CPR), transfer, and surgery, with patients, family members, and surgical consultants. Although age alone is not an indication to withhold aggressive treatment, in select cases with a grave prognosis and when the patient's goals of care are known, comfort measures may be more appropriate than transferring patients to a trauma center.

KEY CONCEPTS

- Older adults are prone to significant injuries with low-force trauma such as falls from standing. Vigilance for occult injuries, including TBI, cervical spine injuries, hip and pelvis fractures, and solid organ injuries, should be maintained.
- Vital signs, including tachycardia and hypotension, are unreliable to detect hemodynamic instability in older adults owing to changes in physiology, comorbidities, and medications. Clinicians should expand their assessment for shock by including alterations in mental status, urine output, and skin perfusion and should have a low threshold for considering shock in elderly trauma patients.
- Elders are at significant risk from shock, yet they are also at risk from overly aggressive resuscitation. Resuscitation should be rapid but should include frequent reassessments of vitals signs, respiratory status, and other potential indicators of shock. Invasive hemodynamic monitoring may be beneficial.
- Clinical decision rules for radiographic imaging have generally excluded elderly patients. A low threshold is advised for imaging in older adults with trauma.

Chapter 40

Injury Prevention and Control

E. Brooke Lerner and Stephen W. Hargarten

PERSPECTIVE

The science of injury control is based on the concept that trauma is like a disease rather than just the consequence of fate or random occurrences. The principles of disease control are applied to injury as they are successfully applied to infectious diseases. Control of a disease as widespread and multifactorial as injury can occur only through broad interdisciplinary effort, including that of medicine, public health, policy makers, law enforcement, educated citizens, and others (Box 40-1).

Emergency medicine plays a pivotal role in the care of injured patients and in injury control. In the United States, approximately one third of all emergency department visits are for the care of injuries, representing 13.3 visits per 100 people per year.[1] Injury is the leading cause of death for many age groups (Table 40-1). In 2004, 29.6 million people were treated in U.S. emergency departments for injuries, of whom 93% were not admitted to the hospital.[2] The medical cost of injury-related medical care in the United States is estimated to be $117 billion annually.[2] Because the emergency care system may be the patient's only contact with the health care system, emergency physicians should provide preventive services in addition to acute medical care for injured patients.[3-5] Emergency physicians work with trauma surgeons, pediatricians, and others to decrease injuries through clinical and policy-relevant research and education.[6]

PRINCIPLES OF THE DISEASE OF INJURY

The major causes of injury include falls, motor vehicle collisions, gunshots, suffocation, and poisonings. Similar to other disease models, injury occurs from the interaction of agent and host through a vector and an environment that is conducive to exposure (Fig. 40-1). *Injury* is a harmful event caused by the acute transfer of energy to a patient that results in tissue and/or organ damage.[7] The energy may be in any form, such as kinetic (e.g., falls and motor vehicle crashes), thermal (e.g., burns and hypothermia), chemical (e.g., poisoning), or electrical (e.g., lightning strike) energy or the absence of energy (e.g., hanging or drowning).[8] Energy is the agent that is delivered to the host (patient) by a vector in an environment with variable risk. Cars and guns are examples of vectors of energy transmission that cause the injury. A car on an icy road is an example of the interaction of the environment and the vector to increase the likelihood of kinetic energy reaching the host and causing injury.

The goal of injury control is to prevent or decrease the transfer of energy to the host by (1) separating the host from the agent through modification of the environment, (2) equipping the host with protection against the agent, or (3) eliminating or modifying the vector that transmits the energy.[8-13]

The first step in the control of injuries is recognizing that injury is preventable. Public perception is that injuries result from accidents or random, unexpected events, similar to the way in which infections were regarded before the discovery of bacteria. As in other diseases, characteristics of the host affect prevention strategies, acute care, and rehabilitation outcomes. These include physical characteristics, such as age, gender, size, and motor skills, and mental or behavioral characteristics, such as intelligence, fatigue, alcohol use, emotional stability, social norms, and lifestyle. Risks for injury and death vary by age (see Table 40-1). For the likelihood of an injury to be decreased, changes in some of these predisposing factors can be made in the host (e.g., through improvement in driving skills or a commitment to wear a seat belt or not to drink and drive) and should be age specific for maximum effect.

Energy is transmitted to the host through a *vector,* such as motorized and nonmotorized vehicles (e.g., car, bicycle, and skateboard), firearms, piercing instruments (e.g., knife and arrow), explosives, and lit cigarettes. Modifying the vector (by elimination or modification of design) and separating the vector from the host are important methods to reduce injury. For example, the understanding of biomechanical forces released during an injury event is crucial to understanding vehicle modification.[14-16] Physicians should educate patients and families to modify or eliminate vectors they encounter during their daily lives—for example, recommending that families properly store household firearms and use gun locks.[17] Another example is storing drugs that look similar in different locations on an ambulance or changing the packaging to reduce the risk of injuries caused by administering the wrong medication.

When an injury occurs, host-agent interaction and energy transfer take place in an *environment.* This environment can be modified to decrease injury. If the environment does not permit energy transmission, the risk of injury, including intentional injuries to the host (patient), is eliminated.[18] Most environmental modifications require no cooperation or action by the host and are more effective than altering host risk factors. Examples are implementing safer road design and lighting to prevent motor vehicle collisions, removing throw rugs to prevent falls, placing fences around pools, and separating bicycle paths from roadways.[12,19]

William Haddon, the first physician administrator for the National Highway Traffic Safety Administration (NHTSA), first described this type of approach in a landmark article on injury control in 1970.[20] He laid out 10 methods for preventing injury (Table 40-2). Haddon later expanded these ideas to incorporate

time and developed the Haddon matrix. The matrix recognizes that preventative interventions should be considered for the host, agent, vector, and environment before the event, during the event, and after the event. Any type or cluster of injuries can be prevented or reduced in severity through use of this matrix when the environment, vector, and population most at risk are identified and modified. An example of this process to reduce motor vehicle collision injuries is given in Table 40-3. The key to energy transfer reduction or prevention is understanding that (1) injuries are predictable, (2) they follow predictable patterns (e.g., by age or gender), and (3) reliance solely on human factors for prevention has significant limits. A fragile item sent through the mail arrives at its destination intact only if it has been properly packaged to reduce the energy to which it is subjected during transport. Likewise, injuries to people can be prevented by use of the cells of the Haddon matrix to mitigate the energy transfer of predictable events.

History of Injury Control

Decreasing personal injury is a goal of modern public health, but until the 1940s and 1950s, unintentional injuries were attributed primarily to human error, and prevention was based on educating people to act safely.[10] Unsafe roads were built, and motorized vehicles and other consumer products were manufactured without regard to safety design flaws.[21] This is analogous to supplying untreated tap water to homes and relying on educating people to purify their drinking water to prevent cholera.[11]

In the 1920s, attributing vehicle crashes to poor driver performance led to mandatory licensing of drivers. In the 1930s, when it was realized that vehicle crashes were caused not simply by human error but by mechanical factors as well, President Roosevelt called for automobiles to be made more crashworthy.[8] In 1942, Hugh DeHaven, a former World War I pilot turned physiologist, pondering his own survival in an airplane crash when another occupant had been killed, suggested structural provisions be made to vehicles that would distribute the forces of energy over the human body to attenuate the energy transfer and reduce injuries in crashes. He focused on defining the physical factors that influence survival rather than the human error that caused the crash.[8] As the United States embarked on its space program, Air Force researchers showed that humans could withstand splashdown with a sled that decelerates from 30 to 0 mph over a stopping distance of 2 feet.[22] This demonstration was a significant advance in understanding the biomechanics of sudden deceleration.

The recognition that injuries could be addressed similarly to diseases occurred in the 1940s, when John Gordon, an epidemiologist, suggested that injuries have epidemic patterns, seasonal variation, long-term trends, and demographic distribution and can be examined with methodologies applied to infectious diseases. Gordon also believed that, similar to infectious diseases, injury results from the interaction of the agent, host, and environment.[8] In the 1960s, Haddon developed a two-dimensional approach to injury analysis by dividing the factors of agent, host, and environment into three phases: preinjury, injury, and postinjury. This phase-factor matrix has become a mainstay of injury control development. Any injury event can be broken down into the component factors, allowing specific interventions to target specific factors (Table 40-4).[12,23]

In 1985, the publication *Injury in America: A Continuing Public Health Problem* by the National Research Council and the Institute of Medicine called on the public health and health care community to address the injury epidemic.[13] With the establishment of the National Center for Injury Prevention and Control (NCIP) in the Centers for Disease Control and Prevention (CDC), it was acknowledged that the control of injuries belongs in the disease control community and includes health care providers such as emergency physicians.

Soon after its inception, the NCIP began sponsoring injury control research centers at academic institutions throughout the country. These centers, frequently led by physicians, including emergency physicians, conduct research in all three core phases of injury control (i.e., prevention, acute care, and rehabilitation) and serve as training centers for injury control specialists and as information centers for the public.[24] To expand this work, the Society for the Advancement of Violence and Injury Research is open to any group or individual with an interest in advancing research in violence and injury (www.savirweb.org).

In 2003 the NCIP began updating the CDC Injury Research Agenda to include acute care research, focusing on research that will improve acute injury care systems.[25] After this, the NCIP Division of Injury and Disability Outcomes and Programs changed its name to the Division of Injury Response, with a mission "to increase the capacity to prevent injuries and their adverse health effects by working with partners to develop, evaluate, and promote evidence-based surveillance, prevention, and care practices."[26] This center became a home for acute injury care and acknowledges its importance for prevention. This division has also become a focal point for response to terrorist-related injuries, an important area of injury control. In 2009 the NCIP published a revised research agenda continuing the Center's commitment to acute care research.[27]

Methods of Prevention

The history of injury control began with the first injury. Pain from injury is a powerful stimulus for avoidance behaviors. Early prevention technology is seen in the instruments and garb of the earliest armies, shielding people from the harmful kinetic energy of weapons. Such technology included helmets, shields, and suits of armor. As the delivery of kinetic energy became more sophisticated, prevention technology did not keep pace.[15,16] Firearms and automobiles represent new plateaus in harnessing kinetic energy as well as creating new sources of morbidity and mortality.[21,28] The cultural belief was that individuals could avoid vehicular injury by safe driving, and if they did not drive safely, an "accident" would occur. It took more than 50 years to acknowledge that behavior modification alone was insufficient to mitigate high-energy

transmission to humans in a hazardous environment. Cars were not uniformly equipped with seat belts until the 1960s.[21] It took another two decades before air bags became standard.[15,16,29]

Implementation of effective injury control strategies depends on collaborative efforts by a number of individuals, including physicians, nurses, out-of-hospital care providers, epidemiologists, biomechanical engineers, public policy makers, law enforcement officers, lawyers, and other stakeholders.[19,29,30] A major challenge is the wide diversity of disciplines and interests involved in safety and injury control, many of which are isolated from one another.[10] In the 1990s, important strides were made in community-based injury control programs that rely on coalitions of existing resources with the support of the NHTSA, the CDC, and the State and Territorial Injury Prevention Directors Association. These community coalitions were created to garner existing resources and implement injury countermeasures through use of "the 3 Es"

Table 40-2 Haddon's Strategies for Preventing the Transfer of Energy to the Host

TECHNIQUE	CAR CRASH	FALLS
1. Prevent the initial marshaling of energy	Manual task, breathalyzer ignition interlocks Use of alternative transportation	Remove floor obstacles Prevent unnecessary climbing
2. Reduce the amount of energy marshaled	Speed reduction Vehicle mass restrictions	Climbing height restrictions
3. Prevent the release of energy	Breakaway light poles, roadway obstacle removal	Ambulation aids for elderly Worker safety harnesses
4. Modify the rate of spatial distribution of the release of energy from its source	Auto body crumple zones Safety belts, air bags Water barrel barriers	Land with a "roll" Use of safety nets
5. Separate the energy from the host in space or time	Reduce traffic density Homogeneous traffic flow Increase following distance Sidewalks for pedestrians	Safety zones at edge of raised work areas
6. Separate the energy from the host by barrier	Guardrails, concrete median barriers	Guardrails for scaffolds, raised work areas
7. Modify the surface or structure of impact	Collapsible steering columns, padded pillars and bolsters, safety glass	Padded flooring Helmets and hard hats
8. Strengthen the host receiving the energy	Detect and treat premorbid medical conditions	Prevent and treat osteoporosis and strengthen hip flexion in elderly patients
9. Rapidly detect and evaluate damage and counter its continuation and extension	911 and EMS availability Trauma system planning and implementations, and provision of state-of-the-art emergency care	911 and EMS availability Trauma system planning and implementation, and provision of state-of-the-art emergency care

INJURY CONTROL IN MEDICAL PRACTICE

Traditionally, physicians have focused on treating the patient after the disease has occurred. As the causes of many diseases have become better understood, education about risk assessment and clinically based prevention has been integrated into medical practice, particularly in infections (immunizations) and cardiovascular disease (smoking cessation). Emergency physicians are incorporating risk assessment, counseling, and referral of patients in high-risk groups for injury, such as those experiencing domestic violence.[3,5] The Joint Commission has emergency department requirements for addressing abused patients.[31]

Emergency care providers are pivotal in the recording and accumulation of data about the injury event, which is useful for surveillance and epidemiologic analysis. Injury control techniques can be incorporated easily into emergency medicine practice as well.[5,32-35] A rational approach to improve injury care in a community (Box 40-2) requires that physicians from a variety of specialties (e.g., emergency physicians, surgeons, pediatricians, and physiatrists) assume specific roles and activities in promoting injury control. This role for emergency physicians in injury control has been advocated by the American College of Emergency Physicians.[36] Documentation of injury information in the medical record, assessment of risk factors in individual patients, counseling and referral, provision of systematized acute trauma care, and public health advocacy are all important.[37-39]

Injury Epidemiology and Documentation

Gathering accurate data is essential to understanding the characteristics of a disease—its endemic populations, cyclic variations, geographic characteristics, and effectiveness of interventions. Consistent and comprehensive data should be gathered across the population of injured patients and used for hypothesis testing,[40,41] hypothesis generation, ongoing monitoring of disease patterns and characteristics,[35,42] and understanding of outcomes of prevention and policy interventions. The goal of injury data collection is to discover who is being injured (host), what is injuring them (vector), and the circumstances surrounding the injury (environment).[43,44]

Until recently, reliable data on the disease of injury were limited to mortality data collected by coroners and medical examiners.[45] The Fatal Analysis Reporting System, a comprehensive data set on all car crash deaths in the United States, was established by the NHTSA in 1975[46] for examination of the epidemiology of motor vehicle crashes.[40]

Because death is uncommon compared with the large number of injured people who receive medical care, conclusions based solely on mortality data are limited.[13,47,48] The advent of trauma registries in the 1980s increased the sample from patients who die to patients admitted to trauma centers. Because these data are skewed toward the most severe injuries, the conclusions based on these data are still limited when generalized to all injured people.[49]

Approximately 93% of injured patients seeking medical care for injury are treated and discharged from the emergency department, and many of them experience significant morbidity resulting in long-term disability and significant cost to society.[13,35,42,47] To capture reliable emergency department data, the CDC developed Data Elements for Emergency Department Systems to define the minimum data set essential for physicians and information systems developers.[50,51] The most crucial data element for the understanding of injury is the *E code,* a system for identifying the cause of injury in a patient's medical record according to the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM).[19] The *E* stands for external cause of injury, such as car crash, fall, or bicycle crash. The cause of injury cannot be extracted from diagnosis codes in medical records. These are N codes—the nature of the injury, such as skull fracture, laceration, or contusion. Because injury control depends on identifying the vector that is causing injuries and not just the resultant injuries, the only way to accomplish this systematically is by documenting the appropriate E code for each patient visit. Several states have mandated documentation of E codes for all emergency department discharges[35,42-44]; however, the completeness of this documentation is variable. The CDC found that 37% of hospital discharges after injuries were missing valid external cause of injury codes.[48]

The greatest barrier to the collection of E codes in the emergency department is inadequate physician documentation to assign accurate E codes retrospectively from the medical record.[47,52,53] The first step in data gathering is complete and legible documentation of the cause of injury in patient medical records. Because injury problems in a community differ greatly from region to region, community-specific injury control efforts can be generated, implemented, and evaluated.[19,41]

E-coded hospital records can provide the *who, what,* and *when* of injury. The question of *where* can be either place of occurrence or place of residence, both of which are important and have implications for planned countermeasures. Hospital records are helpful in determining place of residence of injured patients, which is useful for community education in high-risk neighborhoods. Location-of-injury data are available only from other sources, such as emergency medical services (EMS), police, or other records. These data are more likely to be useful for environmental modification through engineering enhancements, police enforcement, or hazard removal. Linkage of these records to patient visits, either manually for specific research studies or electronically for surveillance, is the next step in gaining a comprehensive understanding of the epidemiology of injury.[54,55] New desktop computer–based geographic information system programs can be used to study injury locations with minimal training and resources. The maps generated by these programs can identify areas with injury clusters to focus prevention efforts on areas with the greatest need.[56,57]

Box 40-2 Injury Control in Emergency Medicine Practice

Clinical Preventive Services

- Document injury information in the medical record
- Ensure that medical records of injury cases contain E codes
- Assess behavioral and comorbid risk factors for future injury
- Provide risk screening, counseling, and referral
- Assess biomechanical risk factors in individual patients
- Use biomechanical risk factors for directed evaluation of injured patients
- Provide systematized acute trauma care

Population Health, Research, and Policy

- Participate in and advocate for inclusive trauma systems
- Direct and advocate for rapid, competent emergency medical services response
- Lead efforts in policy development, implementation, and evaluation
- Lead efforts in educating high-risk groups
- Lead efforts to address and modify the environment to reduce risk of injury
- Collaborate in multidisciplinary research to reduce injury risk and to improve care

www.ketabpezeshki.com 66485457-66963820

Statewide injury data linkages exist in some states and are available for surveillance information[58] and research for unintentional and intentional injuries.[32,41,59] For example, the Crash Outcome Data Evaluation System uses probabilistic linkage to create a database of crash, hospital, EMS, and emergency department information for motor vehicle crashes.[60]

Interest and opportunity to apply injury control principles for medical injuries, also known as *medical errors,* are growing. Medical injuries account for an estimated 50,000 to 98,000 deaths each year in the United States, with hundreds of thousands of nonfatal events occurring in emergency departments, intensive care units, and operating rooms.[45] Emergency physicians can play an important role in use of injury control principles and science to reduce medical injuries.[61-64] Application of injury control principles for the identification of injury patterns and for the development and evaluation of injury prevention strategies has great potential.[63,64]

Risk Factor Assessment

Biomechanical Risk Factors

Biomechanical factors responsible for the injury are challenging to understand, occurring in car crashes or gunshots in less than a 10th of a second. Emergency physicians are not trained in engineering principles and have limited exposure to this "pathophysiology" during training. Ascertaining the forces released on the patient during a blunt injury (car crash or fall) or penetrating injury (gunshot or stabbing) leads to a directed approach to injury management.[65-68] Extensive research has been done with crash dummies, mathematical models, and computer models to understand the mechanical forces applied in injury and human impact tolerance.[15,16] Although used extensively by the engineering community for design of products, such knowledge is also valuable to the emergency physician in guiding evaluation and treatment based on energy transfer, tissue tolerance, and risk of occult injury.[7] Furthermore, as this information becomes more readily available at the time of crash response through automatic crash notification (e.g., General Motor's On-Star system), it will become more important to understand and correctly interpret what it means in terms of potential injuries.[69]

Injury occurs when energy is delivered to the host in levels that exceed tissue and organ tolerance. This energy can be expressed in g-forces. The g-force that results from a motor vehicle crash, for instance, can be expressed with the following formula:

$$g = \Delta v^2/(\text{stopping distance} \times k)$$

where Δv is the change in velocity, *stopping distance* is the distance over which the change in velocity occurs, and k is a constant. The g-force is inversely related to stopping distance. To minimize energy transfer to the body during a motor vehicle collision, one maximizes the stopping distance during the event. The formula shows that doubling the stopping distance reduces the g-force by half, but doubling the speed quadruples the force. Less g-force is applied as velocity is reduced over increasing distance, as the vehicle slows during preimpact braking or deforms during a crash. The same principle underlies engineering features, such as interior padding, collapsible steering columns, water barrel barriers at bridge abutments, and flexible guardrails. All are designed to increase stopping distance, a major principle of automobile and highway safety engineering.[15,16,70]

In the mid-1980s, the air bag was a significant improvement in safety engineering because it resulted in increased occupant stopping distance during a crash, saving nearly 20,000 lives by 2005.[71] Initially, these benefits were confined to frontal crashes, but side curtain air bags have also greatly contributed to the number of lives saved.[72]

As with many new safety countermeasures, there are unintended consequences. First-generation air bags deployed with tremendous force at speeds of 140 to 200 mph over 50 msec.[73] Such forces can be lethal to children in the front passenger seat, especially when unrestrained by safety belts, or seated in rear-facing infant seats.[74,75] A new generation of advanced, less aggressive air bags has been in use since the late 1990s to reduce air bag–associated injuries. It is essential to understand the differences in risk posed by seating position, restraint type and use, and vehicle type when assessing crash victims and to counsel patients properly on safety belt and child restraint use.[40,76] Motor vehicle crashes are the leading cause of death for children older than 24 months in the United States (see Tables 40-4 and Table 40-1). The risk of death in a motor vehicle crash can be reduced by half with the use of age-appropriate child restraints. Every pediatric visit is an opportunity to counsel parents on the safe transport of their children.

In March 2011 the NHTSA revised its recommendations, stating that anyone younger than 13 years should ride only in the rear seats of vehicles.[77] Infant seats should never be positioned in the front seat within range of the air bag. Infants 12 months old or younger should always ride in a rear-facing car seat. Children 1 to 3 years old should ride in a rear-facing seat, and children aged 4 to 7 years should ride in a forward-facing car seat until they outgrow the manufacturer's specifications. A booster seat should be used for children from 8 to 12 years old, allowing for better seat belt positioning and discouraging the child from sitting out of position to see out the windows. If a smaller child must ride in the front passenger seat, that seat should be as far to the rear as possible and a seat belt should always be worn.[78] Federal rules allow for air bags to be disabled if there are circumstances necessitating that small children ride in the front seat and for certain medical conditions.[78] Increasingly, more vehicles are equipped with sensors that turn off the airbag when certain weight thresholds are not met. Physicians caring for short-stature individuals should counsel these patients about the risk of air bag injuries and recommend they sit with at least 10 inches between the sternum and the steering wheel equipped with an air bag. This distance should be measured objectively because people tend not to estimate this distance correctly.[79]

Other safety features have been associated with specific injuries. Automatic "passive" shoulder belts that require manual fastening of the lap portion may result in "submarining" of the torso toward the floorboard when the lap portion is not fastened, while the shoulder belt squeezes the lower rib cage. These devices were associated with liver, spleen, and lung injuries[80] and have been discontinued. However, because cars can be driven over a number of years, it takes many years to completely remove these dangers from the streets. Because automotive safety improves with each new model year, it is important to learn about these safety features and how they might change an injured patient's presentation.

Knowing the contact surface in falls affects diagnostic and therapeutic interventions because soft surfaces increase stopping distance compared with concrete or packed earth.[15,16] Understanding the biomechanical risks of other injuries, such as tissue forces from the ballistics of bullet wounds, can also guide treatment decisions (see Chapter 65).[14,81]

Behavioral and Comorbid Risk Factors

Recognition of patients at high risk of injury affords opportunity for intervention. Counseling a patient about specific ways to avoid injury in the "teachable moment" after injury is more likely to have an effect than diffuse public education.[82] Family or friends can be recruited to enforce the message to patients or to assist patients in modifying their behavior or environment. Other

www.ketabpezeshki.com 66485457-66963820

patient encounters may be used as an opportunity to counsel high-risk patients, such as children at developmental stages that put them at risk for auto versus pedestrian injuries, climbing injuries, or poisoning. It is particularly important to explore the circumstances surrounding injuries to children. A brief review of the injury incident would help physicians and parents identify risks for future injury and opportunities for intervention.[83] Children who come to the emergency department after an injury are likely to be injured again, commonly during falls and motor vehicle crashes.[84] Preschool-age children admitted to the hospital after injury were found to be twice as likely as community controls to have been treated previously in the emergency department for injury and more likely to have an emergency department visit.[85]

Risk factors for intentional injury are complex and involve behavioral, social, and environmental factors, but risk factors for all types of injury include male sex, low income, illicit drug involvement, previous arrest, and young age.[85-87] In studies using psychosocial inventories, recidivists are more likely to have a low sense of autonomy, to have low levels of spirituality, and to have been a crime victim in the past.[85] The most obvious risk factor for future violent injury is prior violent injury. A history of prior significant injury is a strong predictor of injury recidivism, with 10 times the risk of patients with no prior trauma.[87,88] Emergency departments should have protocols in place for the detection and referral of patients likely to be victims of injury in the future, including victims of domestic violence,[3] and for children younger than 18 years injured intentionally, regardless of the age of the perpetrator. In many states, there are mandatory reporting laws for gunshot wounds, stabbings, and other violent acts.[89,90] Interventions provided to injured patients in the health care setting can reduce injury recidivism.[86,91]

In the case of motor vehicle injury, the three behavioral risk factors most likely to result in future injury are speeding, seat belt nonuse, and driving after drinking alcohol. Giving patients the necessary data for them to make an accurate self-assessment about their risks is the essence of patient behavioral intervention.[92] These messages should be part of every injury patient's encounter, when feasible. Particularly important in this context is the screening and referral for alcohol use disorders (AUDs). Alcohol-related crash injury is a national epidemic in the United States, with 32% of all motor vehicle traffic fatalities involving an alcohol-impaired driver.[93] Reductions in alcohol-related deaths as a result of more stringent laws, more vigilant public education, and a societal shift toward the condemnation of driving while impaired have not had significant effects on people with AUD. Of patients seen in the emergency department after a motor vehicle crash, 17 to 20% meet criteria for AUD.[94,95] Patients with AUD have higher rates of illness and motor vehicle crash injury than the rest of the population, and patients with AUD are more likely to drive after drinking.[90]

Emergency physicians have a unique role to play in the identification of high-risk patients. In particular, patients with AUD should be detected and referred for formal evaluation and treatment. A structured approach to detect and treat the disease should be brief and effective if it is to be used in a busy emergency department. Screening techniques validated in the emergency department and methods of brief intervention have been thoroughly described.[90]

Successful treatment of AUD leads to reduction in alcohol consumption and binge drinking and consequently fewer impaired driving episodes, thus leading to a reduction in alcohol-related crash injuries. Being treated for injury in the emergency department may be an important motivational opportunity to reduce drinking and presents a "teachable moment."[90,95-97] The American College of Surgeons Committee on Trauma recommends that all trauma centers screen for alcohol and provide interventions as a "part of routine trauma care."[98]

Acute Care

The acute care component of injury control involves trauma system planning, medical direction of out-of-hospital care, and provision of systematized resuscitative care after the injury, whether it occurs close to or far from a trauma center.[99] A crucial part of injury assessment is identification of local resources for management of the injured patient. Algorithms and agreements to transfer the patient to definitive care should be established to avoid secondary injury from delays in transfer or inappropriate care.[100] Areas with ready availability of trauma physician specialists should have clear protocols in place for use of those resources.[101] For cost-effective care, in-hospital triage criteria should be developed to avoid unneeded overuse of trauma surgery teams.[39,102,103]

Trauma systems can be created that recognize and complement the exigencies of budgetary, geographic, and political constraints that are specific to states or regions, but such flexibility is often impossible when a trauma system is based only on the hospitals that seek trauma center verification or designation.[102]

An *inclusive* trauma care system uses all acute care and rehabilitation facilities that treat injured patients and deals with the issues of community access, EMS dispatch and response, triage, transport and transfer protocols, training, communications, availability of definitive care and rehabilitation, and a data collection system. In an inclusive trauma care system, every injured patient (not just patients who live near trauma centers) is cared for by a part of the system, and every hospital has a role according to the services it can offer, whether it is the expeditious transfer of patients, the treatment of patients without neurotrauma, or the definitive care provided at a trauma center. The system should be designed to monitor patient outcomes and system performance.[104] Level 1 trauma centers improve severe trauma patient outcomes by 25%, demonstrating the value of an inclusive trauma care system.[105]

Out-of-hospital emergency care is an integral part of injury control.[38] EMS response, triage, and treatment are the first critical steps in injury control, and triage protocols should be well established to avoid unnecessary delays in definitive care.[100] The Field Triage Decision Scheme, first developed by the American College of Surgeons and recently updated in collaboration with the CDC, is designed to guide EMS providers in identifying patients who need the resources of a trauma center.[106] EMS providers have a unique vantage point from which to help the trauma physician assess a patient's risk factors for immediate injuries and the risk of injury recurrence. EMS providers can observe the environment for information about mechanism of injury. Accurate reporting of vehicle damage and other environmental circumstances associated with the injury event elucidates important biomechanical risk factors.[107] EMS providers are also involved in primary injury prevention through injury risk identification, documentation of injury data, and safety education programs.[38]

Emergency Medicine Leadership: Advocacy of Public Policy

Passing and enforcing laws are much more effective than education for increasing seat belt and helmet use.[8,29] Emergency physicians and trauma physicians can provide lawmakers with factual information and the perspective of firsthand experience of the effects of injury. Effective prevention interventions and policies with documented cost savings are more likely to occur when sound, scientific studies are made available to policy makers.[108] Most public health regulations and traffic safety laws are under the jurisdiction of state legislatures and local governments. State and local policy makers are generally much more accessible to physicians and in need of local expertise than policy makers at the

www.ketabpezeshki.com 66485457-66963820

federal level. Emergency physicians need to accept an important advocacy role for reducing injuries and value injury control as a professional activity.[6,109,110]

Community education aimed at people not yet injured may be effective when provided by an emergency physician. Emergency physicians are in a leadership role to deliver the message to school systems, local housing authorities, law enforcement, community service organizations, and policy makers.[33,34] Emergency physicians can be effective spokespersons for injury prevention through the news media, especially after a newsworthy event, and can reframe the event from one of personal blame and behavioral failure to a broader biosocial issue that requires environmental and policy interventions.[111]

Public policy also determines where resources are used in a community. Environmental modifications and elimination of hazards are effective but often expensive. In contrast to education and law enforcement, environmental modifications are *passive countermeasures* that do not require any action by people. Such modifications might be lengthening a "walk" signal at a busy intersection to reduce auto-pedestrian injuries, especially in the elderly[112]; increasing lighting in areas where personal assaults occur[18]; or changing a playground surface from hard-packed earth to wood mulch.[113] The need for such modifications may be known only if the physician is alert to the circumstances by asking "How did this happen?" and documenting the location and circumstances of injuries seen in daily practice.

KEY CONCEPTS

- Injury is the second most costly disease to society and the most serious disease of young people.[114]
- Through interdisciplinary research, a better understanding of the epidemiology and biomechanics of injury will lead to new control strategies. These strategies would complement advances in acute care and trauma systems, which improve care to the patient after the injury has occurred.
- Emergency physicians can incorporate injury control techniques into daily practice through clinical prevention services.
- Increasingly, emergency physicians are leaders in addressing and preventing injuries and complex biosocial problems.

Section Two

SYSTEM INJURIES

Chapter 41

Head Injury

William G. Heegaard and Michelle H. Biros

PERSPECTIVE

Epidemiology

The devastating consequences of head injury have been recorded since ancient times. Early neurosurgical records were primarily observational, with very few suggestions for treatment (Fig. 41-1). Despite centuries of investigation and the development of new and better intensive care, we still have not discovered effective therapies that can be applied after the injury to reverse most pathologic aspects of traumatic brain injury (TBI).

In 1996, Congress approved the Traumatic Brain Injury Act (Public Law 104-166), which charged the Centers for Disease Control and Prevention (CDC) with "determining the incidence and prevalence of traumatic brain injury in all age groups in the general population of the United States."[1]

Each year, an estimated 1.7 million people sustain head injury in the United States.[1]

Of these, 1.36 million (1.4% of all emergency department [ED] visits) undergo emergency evaluation, including approximately 470,000 children younger than age 14 years. TBI accounts for 15.1% of all injury-related hospitalizations in the United States. Overall, 80% sustain minor head trauma (Glasgow Coma Scale [GCS] score of 14 or 15), 10% have moderate head injuries (GCS score of 9-13), and 10% have severe head injuries (GCS score of 8). Almost 20% of all head-injured patients are hospitalized, and approximately 52,000 patients die each year from TBI (Table 41-1).

The leading causes of head injury in the civilian population are falls (43.7%) and motor vehicle collisions (MVCs) (21.5%).[1] TBI caused by blasts has been called the signature injury of the wars in Iraq and Afghanistan: TBI of any severity is estimated to affect as many as 10 to 20% of wartime service members.[2-4] Head injury is the leading cause of traumatic death in patients younger than 25 years and accounts for nearly one third of all trauma deaths.[1] Head injury from child abuse is common.[5] New data suggest that with children younger than 12 months of age, TBIs and/or fractures attributable to abuse occurred in 1 of 2000 infants.[6] The CDC estimates that there are at least 5.3 million Americans currently experiencing some degree of disability as a result of TBI. As veterans return to the United States, the number of patients experiencing the consequences of TBI has increased markedly.

These facts confirm that TBI is a major public health problem. The emergency physician sees patients with head injuries of different clinical severity caused by a variety of mechanisms. External physical signs of head trauma only confirm that injury has occurred; they are not always present in the patient who has sustained serious underlying TBI. The ultimate survival and neurologic outcome of the head trauma patient depend on the extent of TBI occurring at the time of injury, alone or in combination with secondary systemic insults, such as hypotension and hypoxia, that worsen the resulting neurochemical and neuroanatomic pathophysiology. Research aimed at reducing or preventing the neurologic consequences of head trauma is ongoing, but currently the clinical outcome after TBI depends on the circumstances of injury and early clinical management aimed at reducing the occurrence of secondary brain insults. No effective intervention has been found to reverse the pathologic events initiated by the traumatic event.

PRINCIPLES OF DISEASE

Anatomy and Physiology

Scalp and Cranium

The scalp consists of five tissue layers. The dermis is the outermost layer and is among the thickest layers of skin on the body. The underlying subcutaneous tissue contains the hair follicles and the rich blood supply of the scalp. The large blood vessels of the scalp do not fully constrict if they are lacerated and can be the source of significant blood loss. The middle scalp layer is the galea, which is made of tough fascial tissue. It contains the occipitofrontalis and temporoparietalis muscles, which move the scalp backward and forward, elevate the eyebrows, and wrinkle the forehead. Under the galea is a loose areolar tissue layer. Because the areolar attachments to the rest of the scalp are loose, scalp avulsions frequently occur through this layer. This is also the site for development of subgaleal hematomas, which can become quite large because blood easily dissects through the loose areolar tissue. The deepest layer of the scalp, the pericranium, is firmly adhered to the skull.

The skull comprises the frontal, ethmoid, sphenoid, and occipital bones and two parietal and two temporal bones. The unique layered architecture of the bones of the skull enhances its strength. Each bone consists of solid inner and outer layers separated by a layer of cancellous bone tissue (the diploë). In adults the bones of the skull average 2 to 6 mm in thickness; the bones in the temporal region are usually the thinnest of the skull.[7] The cranial bones form a smooth outer surface of the skull, but within the cranial vault are many bone protrusions and ridges. Contrecoup injuries and contusions far from the site of head impact often occur as the accelerating brain strikes against these uneven bone surfaces.

The inner aspect of the skull is lined with the periosteal dura, which is a thick connective tissue layer that adheres closely to the bone surface. The inner meningeal layer of the dura is the outermost covering of the brain. This dural membrane reflects back on itself to make folds within the cranial space. These folds serve to

www.ketabpezeshki.com 66485457-66963820

protect and compartmentalize different components of the brain. The midline falx cerebri separates the two cerebral hemispheres from each other. The tentorium cerebelli partitions the cerebellum and brainstem from the cerebral hemispheres. The U-shaped free margin of this dural fold is important in the pathology of the transtentorial herniation syndromes that can complicate severe head injury. Within the margins of the dural reflections, the two dural layers separate to form large dural venous sinuses. Injury to the dural sinuses is associated with significant morbidity and mortality because of the potential for uncontrolled hemorrhage and the difficulty in repairing these structures.

The cranial vault is rigid and nonexpandable, with an average volume in adults of approximately 1900 mL.[8] Cranial contents exit or enter the skull through many foramina. The largest, the foramen magnum, is the site of exit of the brainstem and spinal cord from the cranium.

Figure 41-1. Title page of a 16th-century neurosurgical textbook. (From Fringer S: Origins of Science. New York, Oxford University Press, 2001, p 422.)

Brain and Cerebrospinal Fluid

The brain is a semisolid structure that weighs approximately 1400 g (3 lb) and occupies approximately 80% of the cranial vault. It is covered by three distinct membranes: the meningeal dura, the arachnoid layer, and the pia. The location of traumatic hematomas relative to these membranes defines the pathologic condition and determines the consequences of the injury.

The major divisions of the brain are the cerebrum, cerebellum, and brainstem. Each lobe of the cerebrum is the source of highly specific neurobehavior, and specific injury to each lobe can disrupt normal behavior patterns. The brain is suspended in the cerebrospinal fluid (CSF), which provides some buffering for the brain during trauma. CSF is produced by the choroid plexus, located primarily in the lateral ventricles of the brain. CSF passes from the ventricular system into the subarachnoid space that surrounds the brain and spinal cord. CSF provides a fluid pathway for delivery of substances to brain cells, elimination of the products of brain metabolism, and transport of peptide hormones and hormone-stimulating proteins from their site of production within the central nervous system (CNS) to their peripheral sites of action.

The normal pressure exerted by the CSF is 65 to 195 mm H_2O or 5 to 15 mm Hg. Blood within the ventricles can obstruct the flow of CSF, causing a traumatic hydrocephalus. Brain injury and its complications can also alter the pH of CSF. Because the pH of CSF influences pulmonary drive and cerebral blood flow (CBF), any alteration can produce detrimental neurophysiologic consequences.

Cerebral Hemodynamics

Blood-Brain Barrier. The blood-brain barrier (BBB) maintains the microenvironment of the brain tissue. Extracellular ion and neurotransmitter concentrations are regulated by movement across this barrier. When the BBB is intact, the ability of neuroactive drugs to penetrate into the brain tissue usually depends on their lipid solubility. Post-traumatic cerebral edema and possibly the biomechanics of the injury itself can cause a prolonged disruption of the BBB for up to several hours after trauma.[9,10] Prolonged disruption of the BBB contributes to the development of post-traumatic vasogenic cerebral edema.

The brain has an extremely high metabolic rate, using approximately 20% of the entire oxygen volume consumed by the body. To provide for its high metabolic demands, the brain requires approximately 15% of the total cardiac output. Optimal regional CBF is maintained by the ability of cerebral vessels to alter their diameter in response to changing physiologic conditions.[10] Hypertension, alkalosis, and hypocarbia promote cerebral vasoconstriction; hypotension, acidosis, and hypercarbia cause cerebral vasodilation. In the normal brain, CBF is maintained at constant levels with a mean arterial pressure (MAP) of 60 to

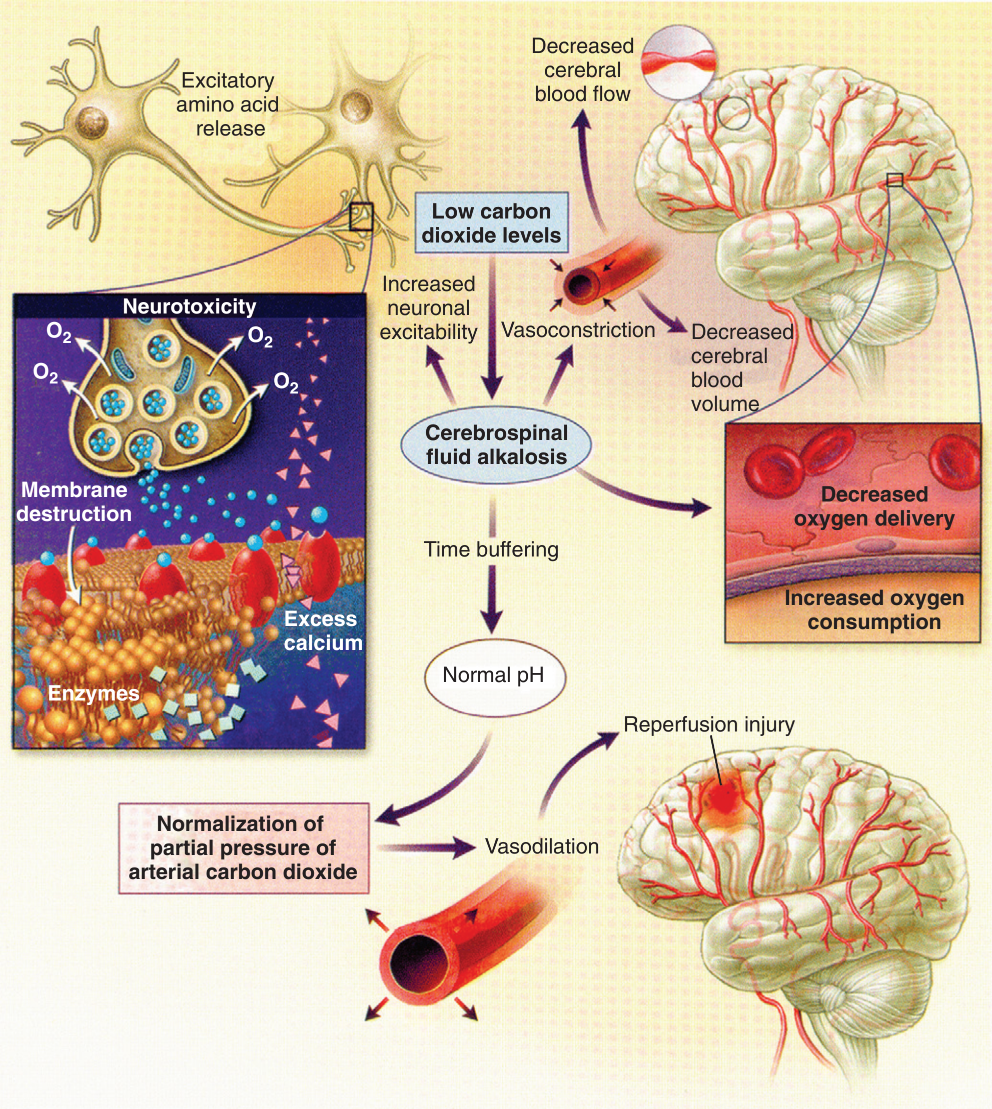

Figure 41-2. Neurologic effects of hypocapnia. Systemic hypocapnia results in cerebrospinal fluid alkalosis, which decreases cerebral blood flow, cerebral oxygen delivery, and, to a lesser extent, cerebral blood volume. The reduction in intracranial pressure may be lifesaving in patients in whom the pressure is severely elevated. However, hypocapnia-induced brain ischemia may occur because of vasoconstriction (impairing cerebral perfusion), reduced oxygen release from hemoglobin, and increased neuronal excitability, with the possible release of excitotoxins such as glutamate. Over time, cerebrospinal fluid pH and hence cerebral blood flow gradually return to normal. Subsequent normalization of the partial pressure of arterial carbon dioxide can then result in cerebral hyperemia, causing reperfusion injury to previously ischemic brain regions. (From Laffey JG, Kavanagh BP: Hypocapnia. N Engl J Med 347:43, 2002.)

150 mm Hg. This is referred to as *autoregulation*. Outside this range, the CBF varies linearly with MAP.

Cerebral vasoactivity is very sensitive to changes in systemic carbon dioxide and oxygen partial pressures (P_{CO_2} and P_{O_2}, respectively). The response to changes in P_{CO_2} is nearly linear between P_{CO_2} values of 20 and 60 mm Hg.[11] In this range, lowering P_{CO_2} by as little as 1 mm Hg decreases the diameter of cerebral vessels by 2 or 3%, which corresponds to an overall change in CBF of 1.1 mL per 100 g of tissue per minute. The physiologic response of blood vessels to P_{CO_2} is the rationale for the acute use of brief hyperventilation to control increased intracranial pressure (ICP) after head injury. As P_{CO_2} decreases with hyperventilation, cerebral vasoconstriction occurs. As a result, the volume of blood per unit area of brain tissue decreases. This decrease (even if small) may buffer the effects of increasing edema or an expanding hematoma within the rigid cranial vault. The vasoconstriction produced by extreme changes in P_{CO_2} (20 mm Hg or less) can be so pronounced that some areas of brain experience ischemia; subsequently, tissue hypoxia can occur.[10,12,13] Therefore hyperventilation is controlled and monitored, with a goal of maintaining the P_{CO_2} between 30 and 35 mm Hg during prolonged hyperventilation, and is reserved for patients who are showing signs of acute herniation.[12,13] Over 12 to 24 hours, injured vessels may lose their responsiveness to hyperventilation-induced hypocarbia and become vasodilated. Blood may then be shunted to the injured area, resulting in increased brain swelling and mass effect. Prolonged (i.e., beyond the acute resuscitation) or prophylactic hyperventilation is therefore not recommended as a treatment for increased ICP, and hyperventilation is not used for the routine management of head-injured patients with no signs of increased ICP.[12,13] The neurologic effects of hypocapnia are illustrated in Figure 41-2.

The cerebral vessels also respond to changes in P_{O_2}. As P_{O_2} declines, cerebral vessels dilate to ensure adequate oxygen delivery to brain tissue. When brain injury has occurred, increased CBF in the presence of a disrupted BBB can promote the formation of vasogenic edema. Avoiding or reversing hypoxia is therefore an essential goal in the acute management of the head-injured patient.[14] The responses of the cerebral vasculature to changing

www.ketabpezeshki.com 66485457-66963820

physiologic conditions protect the brain by increasing the delivery of oxygen to tissue, enhancing the removal of metabolic end products, and allowing nearly instantaneous adjustments of regional blood flow to meet the changing metabolic demands.

Cerebral Perfusion Pressure. CBF also depends on cerebral perfusion pressure (CPP), which is the pressure gradient across the brain. The determinants of CPP are MAP and the resistance to CBF produced by mean systemic venous pressure and ICP. Because ICP is higher than mean systemic venous pressure, ICP effects predominate. Therefore CPP is estimated as

$$CPP = MAP - ICP$$

CBF remains constant when CPP is 50 to 160 mm Hg. If CPP falls below 40 mm Hg, the autoregulation of CBF is lost, CBF declines, and the resultant tissue ischemia critically affects cerebral metabolism. It is essential to avoid or correct hypotension in the patient with multiple trauma who is also head injured so that the CPP can be maintained. Management is also directed at reducing or preventing increased ICP to ensure adequate CPP to sustain cerebral metabolic needs.

Biomechanics of Head Trauma

Direct Injury. Direct impact head injury occurs when the head is struck by an object or its motion is arrested by another object. The resulting damage depends on the consistency, mass, surface area, and velocity of the object striking the head. Direct injury can also be caused by compression of the head. External signs of trauma are frequently noted at the site of application of the impact or compression force. The skull initially bends inward at the point of contact. If the force is sufficient, a skull fracture can occur. The cranium absorbs some of the applied energy, and some energy is transmitted to the brain by shock waves that travel distant to the site of impact or compression. These shock waves distort and disrupt intracranial contents and temporarily alter regional ICP as they propagate. In general, the more rapidly a force is applied, the greater the damage it causes. The extent of direct injury depends on the vasoelastic properties of the underlying region of brain tissue, the duration of the force applied, the magnitude of the force reaching the brain tissue, and the surface area of the brain that is affected by the application of the force. In cases of penetrating trauma, the mass, shape, direction, and speed of the penetrating object also affect the extent of direct injury.

Direct injury from compression of the head requires significant force because the architecture of the skull provides substantial resistance to deformation. In the clinical setting, compression injury is less common than other types of direct impact. With sufficient and prolonged application of compression force, the ability of the skull to absorb the force is overcome, and multiple linear skull fractures occur. Resulting fractures can be depressed if a high-energy rapid compression force is applied to a small area of the skull. Isolated direct impact injury is rare; direct impact usually sets the head in motion, resulting in simultaneous direct and indirect injury.

Indirect Injury. In indirect brain injury, the cranial contents are set into motion by forces other than the direct contact of the skull with another object. A common example is acceleration-deceleration injury, such as the shaken impact syndrome.[15,16] No direct mechanical impact is sustained, but the cranial contents are set into vigorous motion. The brain moves within the skull, and bridging subdural vessels are strained. Subdural hematomas (SDHs) may result. Differential acceleration of the cranial contents occurs, depending on the physical characteristics of the brain region. As one brain region slides past another, shear and strain injuries are produced. This movement results in diffuse injuries, such as diffuse axonal injury (DAI) or concussion. Additional injury occurs as the movement of the intracranial contents is abruptly arrested and the brain strikes the skull or a dural structure. Contrecoup contusions are an example of the injury produced in this manner. In penetrating injury the traversal of the object produces pressure waves that can strike structures distal to the path of the missile.

Brain Cellular Damage and Death

Primary and Secondary Brain Injuries

The acute clinical picture of the patient with TBI is dynamic and represents the sum of primary and secondary injury. Primary brain injury is mechanical damage that occurs at the time of head trauma and includes brain lacerations, hemorrhages, contusions, and tissue avulsions. On the microscopic level, primary injury causes permanent mechanical cellular disruption and microvascular injury. Other than the evacuation of traumatic hematomas, no specific intervention exists to repair or reverse primary brain injury; the only way to reduce the incidence of primary brain injury is through public health interventions aimed at reducing the occurrence and severity of head trauma.

The circumstances and extent of the primary injury are not the only contributors to the final neurologic outcome after head injury. The traumatic event also produces injury at the functional and anatomic cellular level, which begins soon after the impact and continues for several hours and even days after injury. Secondary brain injury results from intracellular and extracellular derangements that are probably initiated at the time of trauma by a massive depolarization of brain cells and subsequent ionic shifts.[17] Animal studies have revealed a complicated series of neurochemical, neuroanatomic, and neurophysiologic reactions after head injury (Fig. 41-3). The cell has some compensatory mechanisms to protect itself from widespread damage, such as endogenous free radical scavengers and antioxidants. With significant trauma, however, these systems are quickly overwhelmed, and the functional and structural integrity of the cell is threatened. Human studies document similar changes. The relative importance and contribution of each adverse reaction to the final functional status of the damaged cell are uncertain, as are the rate and duration of each detrimental event. All currently used acute therapies for TBI

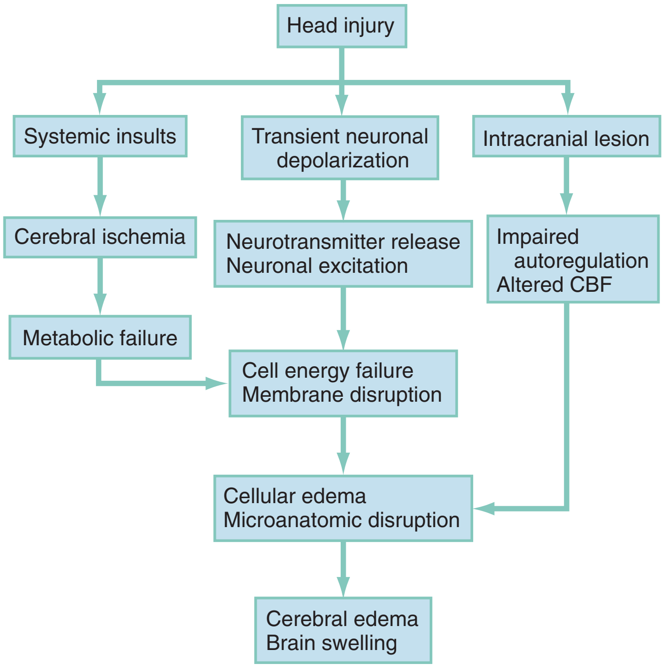

Figure 41-3. Contributing events in the pathophysiology of secondary brain injury. *CBF,* cerebral blood flow.

www.ketabpezeshki.com 66485457-66963820

are directed at reversing or preventing secondary injury. Experimental evidence for many investigational agents aimed at specific steps in the destructive processes suggests that some aspects of secondary brain injury may be reversed or modified. Multiple ongoing head injury trials have been performed with numerous investigational therapeutic interventions; to date, none have proved useful in the clinical setting.[18,19]

Secondary Systemic Insults

The final neurologic outcome after head trauma is influenced by the extent and degree of secondary brain injury. In turn, the amount of secondary brain injury depends on certain premorbid and comorbid conditions, such as the age of the patient and trauma-related systemic events.[19-21] A primary goal in the emergency care of the head-injured patient is prevention or reduction of systemic conditions that are known to worsen outcome after TBI.

Common secondary systemic insults in trauma patients include hypotension, hypoxia, and anemia and hyperpyrexia. *Hypotension,* defined as a systolic blood pressure less than 90 mm Hg, has been found to have negative impact on severe head injury outcome.[18,19,21,22] Systemic hypotension reduces cerebral perfusion, thereby potentiating ischemia and infarction. The presence of hypotension nearly doubles the mortality from head injury and worsens the outcome of the patients who survive.[17,21-23]

Hyperpyrexia (core body temperature of 38.5° C) is also correlated with worsened outcomes after TBI, and both its magnitude and its duration seem to contribute. The exact mechanism by which it causes damage is yet to be determined but likely involves stimulation of metabolism in injured areas of the brain, thus recruiting blood flow with a resultant increase in ICP.[18,21]

Hypoxia, defined as a Po_2 less than 60 mm Hg, probably occurs often in the head-injured patient. Causes include (1) transient or prolonged apnea caused by brainstem compression or injury after the traumatic event; (2) partial airway obstruction caused by blood, vomitus, or other debris in the airway of the traumatized patient; (3) injury to the chest wall that interferes with normal respiratory excursion; (4) pulmonary injury that reduces effective oxygenation; and (5) ineffective airway management, such as the inability to bag-valve-mask or intubate the patient in an effective or timely manner. The exact incidence of hypoxia in the head-injured patient is difficult to estimate because it is often unnoticed or undocumented in the out-of-hospital setting. When its occurrence is documented, the overall mortality from severe head injury may double.[18,22-24] Increased recognition of the potentially devastating consequences of hypoxia and associated hypercarbia has led to more vigilance in out-of-hospital and emergency settings.

Anemia caused by blood loss can be detrimental to the head-injured patient by reducing the oxygen-carrying capacity of the blood, thus reducing the amount of necessary substrate delivered to the injured brain tissue. When anemia (hematocrit 30%) occurs in patients with severe head injury, the mortality rate increases.[18,21] Other potential reversible causes of systemic insult in head injury include hypercarbia, coagulopathy, and seizures.

Pathophysiology

Increased Intracranial Pressure

ICP represents a balance of the pressures exerted by the contents of the cranial cavity. This relationship is explained by the Monro-Kellie doctrine.[25,26] Because the craniospinal intradural space is almost nonexpandable, the sum of the volume of brain, CSF, and blood within the cranium will remain constant. If the volume of any of these components increases, the volume of another must decrease for a constant ICP to be maintained. Increased ICP is defined as CSF pressure greater than 15 mm Hg (or 195 mm H_2O) and is a frequent consequence of severe head injury. Initially, as ICP increases as a result of a traumatic mass lesion or edema formation, the CSF is displaced from the cranial vault to the spinal canal, offsetting the increased blood or brain volume. When this compensatory mechanism is overwhelmed, the elastic properties of the brain substance allow tissue compression to provide buffering for the increasing pressure. Depending on the location and the rate of expansion of the traumatic mass lesion and the rate of cerebral edema formation, the intracranial compensatory mechanisms can accommodate an increased volume of 50 to 100 mL. Beyond that, even small additional changes in intracranial volume relationships, such as those caused by vasodilation, CSF obstruction, or small areas of focal edema, cause a dramatic increase in ICP. If ICP increases to the point at which CPP is compromised, vasoparalysis occurs and autoregulation is lost. The CBF then depends directly on the systemic MAP. With the loss of autoregulation, massive cerebral vasodilation occurs. Systemic pressure is transmitted to the capillaries, and the outpouring of fluids into the extravascular space can contribute to vasogenic edema and thus further increase ICP. If ICP rises to the level of the systemic arterial pressure, CBF ceases and brain death occurs.

Methods to reduce elevated ICP include hyperventilation, use of osmotic and diuretic agents, and CSF drainage. Uncontrollable increased ICP is defined as an ICP of 20 mm Hg or higher refractory to treatment. If ICP is not controlled, herniation syndromes can occur, resulting in brainstem compression and subsequent cardiorespiratory arrest. In the United States, the use of ICP monitoring and control has become standard in cases of moderate and severe TBI despite the lack of prospective controlled research showing clear efficacy as an individual patient treatment modality.[18]

Brain Swelling and Cerebral Edema

Two primary types of brain swelling occur after head injury: congestive brain swelling and cerebral edema. *Congestive brain swelling* results from an increased intracranial blood volume. Hyperemia occurs early after trauma and can persist for the first few days after injury.[23,27] It is especially common in children. The increased blood volume is most likely caused by vasodilation, which occurs as a compensatory mechanism to maintain optimal CBF in the presence of increased metabolic needs of the damaged brain tissue.

Cerebral edema is an increase in brain volume caused by an absolute increase in cerebral tissue water content. Diffuse cerebral edema may develop soon after head injury; however, its presence and extent do not always correlate with the severity of head injury. On computed tomography (CT) scans, diffuse edema manifests as bilateral compression of the ventricles, loss of definition of the cortical sulci, or effacement of the basal cisterns (Fig. 41-4). Focal edema adjacent to traumatic mass lesions demonstrates decreased density on CT scans compared with normal tissue. CT can also detect a *mass effect,* caused by edema surrounding a traumatic lesion.

Both vasogenic and cytotoxic cerebral edema occur in the setting of trauma; the incidence and onset of each relative to the other depend on the nature of the injury. *Vasogenic edema* arises from transvascular leakage caused by mechanical failure of the tight endothelial junctions of the BBB.[23,27] Vasogenic edema accumulates preferentially in white matter and can become widespread. It is frequently associated with focal contusions or hematomas. Vasogenic edema eventually resolves as edema fluid is reabsorbed into the vascular space or the ventricular system.

www.ketabpezeshki.com 66485457-66963820

Figure 41-4. Non–contrast-enhanced computed tomography scan showing diffuse cerebral edema. Loss of gray-white differentiation in brain parenchyma is present. Bilateral compression of the ventricles has occurred with loss of cortical sulci.

Cytotoxic edema is an intracellular process that results from membrane pump failure. It is common after head injury and is frequently associated with post-traumatic ischemia and tissue hypoxia. Normal membrane pump activity depends on adequate CBF to ensure adequate substrate and oxygen delivery to brain tissue. If the CBF is reduced to 40% or less of baseline, cytotoxic edema begins to develop. If CBF drops to 25% of baseline, membrane pumps fail and cells begin to die. Congestive brain swelling can contribute to cytotoxic edema if it becomes severe enough to increase ICP and reduce CPP so that cerebral circulation cannot be maintained. Recent work suggests that cytotoxic cerebral edema is the predominant form of edema in patients who have experienced TBI.[23,28]

Altered Levels of Consciousness

Consciousness is the state of awareness of the self and of the environment, and it requires intact functioning of the cerebral cortices and the reticular activating system (RAS) of the brainstem. An altered level of consciousness is the hallmark of brain insult from any cause and results from an interruption of the RAS or a global event that affects the cortices of both hemispheres.

A patient who has sustained TBI typically has an altered level of consciousness. Head trauma patients may be hypoxic from injury to respiratory centers or from concomitant pulmonary injury. Hypotension from other associated injuries can compromise CBF and affect consciousness. Global suppression may result from an intoxicant consumed before the injury, hypoglycemia, a post-traumatic seizure (PTS), or a postictal period after a seizure from any cause. With increasing ICP from brain swelling or an expanding mass lesion, brainstem compression and subsequent RAS compression can occur.

Patients with altered levels of consciousness require careful monitoring and observation. Reversible conditions that can alter mental status, such as hypoxia, hypotension, or hypoglycemia, should be corrected as they are identified.

Cushing's Reflex

Progressive hypertension associated with bradycardia and diminished respiratory effort is a specific response to acute, potentially lethal increases in ICP. This response is called *Cushing's reflex* or *Cushing's phenomenon,* and its occurrence indicates that the ICP has reached life-threatening levels. Cushing's reflex can occur whenever ICP is increased, regardless of the cause. The full triad of hypertension, bradycardia, and respiratory irregularity is seen in only one third of cases of life-threatening increased ICP.[23,29]

Cerebral herniation occurs when increasing cranial volume and ICP overwhelm the natural compensatory capacities of the CNS (Fig. 41-5). Increased ICP may be the result of post-traumatic brain swelling, edema formation, traumatic mass lesion expansion, or any combination of the three. When increasing ICP cannot be controlled, the intracranial contents shift and herniate through the cranial foramen. Herniation can occur within minutes or up to days after TBI. When the signs of herniation syndrome are present, however, mortality approaches 100% without rapid implementation of temporizing emergency measures and definitive neurosurgical therapy.

Uncal Herniation. The most common clinically significant traumatic herniation syndrome is uncal herniation, a form of transtentorial herniation. Uncal herniation is often associated with traumatic extra-axial hematomas in the lateral middle fossa or the temporal lobe. The classic signs and symptoms are caused by compression of the ipsilateral uncus of the temporal lobe on the U-shaped edge of the tentorium cerebelli as the brain is forced through the tentorial hiatus. As compression of the uncus begins, the third cranial nerve (CN) is compressed; anisocoria, ptosis, impaired extraocular movements, and a sluggish pupillary light reflex develop on the side ipsilateral to the expanding mass lesion. This phase may last for minutes to hours, depending on how rapidly the expanding lesion is changing. As the herniation progresses, compression of the ipsilateral oculomotor nerve eventually causes ipsilateral pupillary dilation and nonreactivity.

Initially in the uncal herniation process, motor examination findings can be normal, but contralateral Babinski's responses develop early.[23] Babinski's sign is dorsiflexion of the great toe and fanning of the other toes. Contralateral hemiparesis develops as the ipsilateral peduncle is compressed against the tentorium. With continued progression of the herniation, bilateral decerebrate posturing eventually occurs; decorticate posturing is not always seen with the uncal herniation syndrome. Pupillary dilation and nonreactivity are the most reliable physical examination findings with regard to lesion location.

In a certain percentage of TBI patients, the contralateral cerebral peduncle is forced against the opposite edge of the tentorial hiatus. Hemiparesis is then detected ipsilateral to the dilated pupil and the mass lesion. This is termed *Kernohan's notch syndrome* and causes false-localizing motor findings. As uncal herniation progresses, direct brainstem compression causes additional alterations in the level of consciousness, respiratory pattern, and cardiovascular system. Mental status changes may initially be quite subtle, such as agitation, restlessness, or confusion, but soon lethargy occurs with progression to frank coma. The patient's respiratory pattern may initially be normal, followed by sustained hyperventilation. With continued brainstem compression, an ataxic respiratory pattern develops. The patient's hemodynamic status may change, with rapid fluctuations in blood pressure and cardiac conduction. Herniation that is uncontrolled progresses rapidly to brainstem failure, cardiovascular collapse, and death.

Central Transtentorial Herniation. The central transtentorial herniation syndrome is demonstrated by rostrocaudal neurologic deterioration caused by an expanding lesion at the vertex or the frontal or occipital pole of the brain. It is less common than uncal

www.ketabpezeshki.com 66485457-66963820

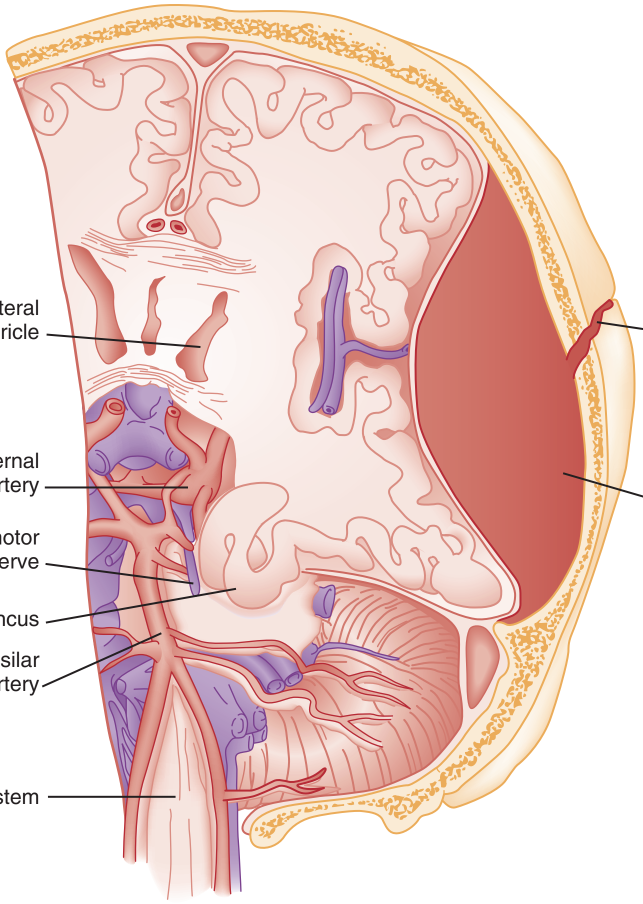

Figure 41-5. Anterior view of transtentorial herniation caused by large epidural hematoma. Skull fracture overlies hematoma. (From Rockswold GL: Head injury. In Tintinalli JE, et al [eds]: Emergency Medicine. New York, McGraw-Hill, 1992, p 915.)

transtentorial herniation. Clinical deterioration occurs as bilateral central pressure is exerted on the brain from above. The initial clinical manifestation may be a subtle change in mental status or decreased level of consciousness, bilateral motor weakness, and pinpoint pupils (2 mm). Light reflexes are still present but are often difficult to detect. Muscle tone is increased bilaterally, and bilateral Babinski's signs may be present. As central herniation progresses, both pupils become midpoint and lose light responsiveness. Respiratory patterns are affected, and sustained hyperventilation may occur. Motor tone increases. Decorticate posturing is elicited by noxious stimuli. This progresses to bilateral decorticate and then spontaneous decerebrate posturing. Respiratory patterns initially include yawns and sighs and progress to sustained tachypnea, followed by shallow slow and irregular breaths immediately before respiratory arrest.

Cerebellotonsillar Herniation. Cerebellotonsillar herniation occurs when the cerebellar tonsils herniate downward through the foramen magnum. This is usually caused by a cerebellar mass or a large central vertex mass causing the rapid displacement of the entire brainstem.[23] Clinically, patients demonstrate sudden respiratory and cardiovascular collapse as the medulla is affected. Pinpoint pupils are noted. Flaccid quadriplegia is the most common motor presentation because of bilateral compression of the corticospinal tracts. Mortality from cerebellar herniation approaches 70%.[23]

Upward Transtentorial Herniation. Upward transtentorial herniation occasionally occurs as a result of an expanding posterior fossa lesion. Level of consciousness declines rapidly. These patients may have pinpoint pupils from compression of the pons. Downward conjugate gaze is accompanied by the absence of vertical eye movements.

CLINICAL FEATURES AND DIAGNOSTIC STRATEGIES

History

Details regarding the mechanism of injury should be solicited from witnesses or the victim to determine whether the head-injured patient is at high risk for intracranial injury. The patient's condition before trauma may give clues to important, otherwise unsuspected, comorbid factors such as preexisting coagulopathy (e.g., hemophilia). Past medical history, medications (particularly anticoagulants), recent drug or alcohol use, and complaints immediately before the traumatic event should be determined.

The patient's current level of consciousness, as well as that immediately before and after the injury and at the arrival of first responders, should be determined. Witnessed PTSs or apnea should be reported. If the patient is now awake but was unconscious at some point, it should be determined if the patient has returned to baseline mental status.

Acute Neurologic Examination

General

The goals of the acute neurologic assessment of head-injured patients include detection of life-threatening injuries and identification of neurologic changes in the immediate post-trauma period. An awake, stable patient can undergo a relatively complete neurologic examination. In other patients, an efficient neurologic examination in the emergency setting includes evaluation of mental status, GCS score, pupillary size and responsiveness, and

www.ketabpezeshki.com 66485457-66963820

motor strength and symmetry. An accurate neurologic assessment in the immediate post-trauma period serves as a basis for comparison in subsequent examinations. If a formal GCS measure is not possible or is difficult because of comorbid confounders, the patient's mental status should be described in as much detail as possible. Declining mental status after head trauma suggests increasing ICP from an expanding mass lesion or worsening cerebral edema, which may rapidly become life-threatening.

Glasgow Coma Scale

The GCS is an objective method of following the patient's neurologic status (Table 41-2). The GCS assesses a patient's best eye, verbal, and motor responsiveness. It was developed for the clinical evaluation of head trauma patients at 6 hours after trauma, and all initial validation studies investigated its application at this time. It was designed for assessment of patients with isolated head trauma who were hemodynamically stable and adequately oxygenated.[26] The GCS is only one aspect of the neurologic examination (e.g., the motor score reflects best limb movement, and it cannot detect subtle changes in mental status). However, because of its inter-rater reliability, reliance on objective clinical data, and ease of application, the GCS has become a standard acute measure of neurologic function in patients with altered mental status from any cause, including head trauma.

The acute application (within 6 hours) of the GCS in head-injured patients has limitations. Hypoxia, hypotension, and intoxication can falsely lower the initial GCS score.[26] Intubation lowers the patient's GCS score by automatically assigning a score of 1 for verbal response, regardless of the actual contribution of head injury to the clinical examination. Periorbital edema from direct eye trauma may make assessment of spontaneous eye opening difficult. Extremity fractures or occult spinal cord injuries may interfere with the motor examination. Children and patients with difficulty communicating are challenging to assess with the GCS. The GCS may miss subtle mental status changes and does not assess brainstem reflexes or pupillary reflexes. Decisions regarding continued resuscitation of severely head-injured patients should not be based on the initial GCS score because of these limitations. Patients should be fully resuscitated, with evacuation of all surgical lesions, and remain hemodynamically stable, and not be intoxicated before the GCS can be used to predict their prognosis.[26]

Table 41-2 Glasgow Coma Scale

RESPONSE	SCORE	SIGNIFICANCE
Eye Opening		
Spontaneously	4	Reticular activating system is intact; patient may not be aware
To verbal command	3	Opens eyes when told to do so
To pain	2	Opens eyes in response to pain
None	1	Does not open eyes to any stimuli
Verbal Stimuli		
Oriented, converses	5	Relatively intact CNS, aware of self and environment
Disoriented, converses	4	Well articulated, organized, but disoriented
Inappropriate words	3	Random exclamatory words
Incomprehensible	2	Moaning, no recognizable words
No response	1	No response or intubated
Motor Response		
Obeys verbal commands	6	Readily moves limbs when told to
Localizes to painful stimuli	5	Moves limb in an effort to remove painful stimuli
Flexion withdrawal	4	Pulls away from pain in flexion
Abnormal flexion	3	Decorticate rigidity
Extension	2	Decerebrate rigidity
No response	1	Hypotonia, flaccid: suggests loss of medullary function or concomitant spinal cord injury

CNS, central nervous system.

Pupillary Examination

An evaluation of the patient's pupil size and responsiveness is performed early in the initial assessment of the head-injured patient. Pupillary asymmetry, the loss of the light reflex, or a dilated pupil suggests herniation syndrome. Traumatic mydriasis, resulting from direct injury to the eye and periorbital structures, may confuse the assessment of the pupillary responsiveness.

Motor Examination: Posturing

The patient's acute motor examination assesses for strength and symmetry. Paralysis obscures involuntary reflexes; attempts should be made to perform the motor examination before paralytic agents are given. Hemiparesis contralateral to a fixed and dilated pupil suggests herniation syndrome. A false-localizing motor examination can be caused by contralateral cerebral parenchymal injury occurring simultaneously with the expanding mass lesion or by Kernohan's notch syndrome (compression of the contralateral cerebral peduncle). False-localizing motor signs can also be caused by extremity trauma, spinal cord, or nerve root injury that makes the examination painful or difficult. If the patient is not cooperative or is comatose, motor movement should be elicited by application of noxious stimuli. Any movement should be recorded. Voluntary purposeful movement must be distinguished from abnormal motor posturing. *Decorticate posturing* is abnormal flexion of the upper extremity and extension of the lower extremity. The arm, wrist, and elbow slowly flex, and the arm is adducted. The leg extends and internally rotates, with plantar flexion of the foot. Decorticate posturing implies injury above the midbrain. *Decerebrate posturing* is the result of a more caudal injury and therefore is associated with a worse prognosis.[19] The arms extend abnormally and become adducted. The wrist and fingers are flexed, and the entire arm is internally rotated at the shoulder. The neck undergoes abnormal extension, and the teeth may become clenched. The leg is internally rotated and extended, and the feet and toes are plantar flexed.

Brainstem Function

In the acute setting, brainstem activity is assessed by the patient's respiratory pattern, pupillary size, and eye movements. The *oculocephalic response* (doll's eyes maneuver) tests the integrity of the pontine gaze centers. This response cannot be tested until cervical spine fractures have been ruled out. The *oculovestibular response* (cold water calorics) also permits assessment of the brainstem. Comatose patients no longer demonstrate nystagmus when cold water is placed in the ear canal; the only response is tonic deviation of the eyes toward the instilled cold water.[24] This response is dampened by cerumen or blood in the patient's ear canal, and the tympanic membrane needs to be intact for this test to be performed.

www.ketabpezeshki.com 66485457-66963820

Box 41-1 Clinical Characteristics of Basilar Skull Fractures

Blood in ear canal
Hemotympanum

- Decreased auditory acuity
- Dizziness
- Tinnitus
- Nystagmus

In the severely head-injured patient, the CN examination is often limited to the pupillary responses (CN III), gag reflex (CNs IX and X), and corneal reflex (CNs V and VII). Facial symmetry (CN VII) can sometimes be assessed if the patient grimaces with noxious stimuli. In patients who are awake and cooperative, a formal CN examination should be performed.

Deep Tendon Reflexes and Pathologic Reflexes

Tendon reflexes should be tested for symmetry. An extensor plantar reflex (Babinski's sign) is nonspecific and can be caused by injury anywhere along the corticospinal tract. Rectal sphincter tone and anal reflexes should be determined to assess for spinal cord integrity.

Other Examination Findings

The head and neck should be carefully examined for external signs of trauma that may have also produced underlying TBI. A scalp laceration, contusion, abrasion, or avulsion may overlie a depressed skull fracture. Basilar skull fractures are usually diagnosed by the clinical examination (Box 41-1). Although not always related to severe brain injury, their presence implies that a significant impact force was sustained during head trauma. Carotid artery dissections caused by a hyperflexion-extension neck injury can occasionally be detected by auscultation of a carotid bruit.[24] In these patients, a careful neurologic examination should assess for subtle asymmetry between the carotid arteries. The percentage of concurrent cervical spine injury in patients with severe head trauma may be as high as 10.2%.[27] Often, other spinal regions are also injured.

MANAGEMENT

Severe Traumatic Brain Injury

The neurosurgical literature defines severe head injury as TBI manifested by a postresuscitation GCS score of 8 or lower within 48 hours. In the emergency setting, however, this definition is not practical because the outcome for the patient beyond the initial resuscitation is not known. Most emergency medicine research defines severe head injury by a GCS score of 8 or lower at the acute presentation after injury. The presence of any intracranial contusion, hematoma, or laceration is also considered severe injury (see Fig. 41-5).

Approximately 10% of all head-injured patients who reach the ED alive have severe head trauma.[1,30] The clinical prognostic indicators in the acute setting are initial motor activity, pupillary responsiveness, the patient's age and premorbid condition, and the occurrence of secondary systemic insult during the acute period.[23,28,31] Up to 25% of these patients have lesions requiring neurosurgical evacuation.[18] The prognosis cannot be reliably predicted by the initial GCS score or initial CT scan.

The overall mortality in severe head trauma has improved over the years and now remains stable at approximately 35%.[32,33] Mortality for children is lower. For nonsurvivors of head injury who reach the hospital alive, the average time to death is 2 days after trauma. Adult survivors of severe head trauma are usually severely disabled; currently, only 7% have moderate disability or a good outcome. Children older than 2 years who survive a severe closed head injury have a better outcome than adults.

Out-of-Hospital Care

The goals of out-of-hospital management of the head-injured patient are the necessary airway interventions to prevent hypoxia and the establishment of intravenous access to treat trauma-related hypotension. An accurate neurologic assessment provides a means to determine the subsequent effectiveness of treatment and should focus on the GCS score, pupillary responsiveness and size, level of consciousness, and motor strength and symmetry.

Head trauma can produce profound effects on the cardiovascular system if compression of the brainstem and medulla occurs. Any cardiac dysrhythmia can occur and produce cardiac instability.[23,34] All head-injured patients should be placed on a cardiac monitor during transport from the accident scene.

The secondary survey of the head-injured patient should include a search for external signs of head trauma. Scalp lacerations may bleed a large volume into a bulky dressing. A less bulky dressing should be used with firm constant manual pressure applied to avoid excessive blood loss. Many severely head-injured patients are initially combative or agitated. Transporting an agitated patient who is fighting against physical restraints may exacerbate physical injury, cause an increase in ICP, and interfere with appropriate stabilization and management. It may be necessary to use out-of-hospital sedation or neuromuscular blockade for control. The use of sedatives or neuromuscular blockade may influence the initial ED evaluation of the neurotrauma patient. Therefore the risks and benefits of this acute intervention are carefully considered and decisions made on a case-by-case basis. Out-of-hospital protocols allowing the use of sedative agents for selected agitated head-injured patients should be established. Currently used agents include lorazepam (Ativan), diazepam (Valium), midazolam (Versed), and certain butyrophenones (e.g., haloperidol, droperidol). Some investigators are looking at the use of ketamine for prehospital sedation in combative head-injured patients. Recent research questions whether the widely held belief that ketamine increases ICP and CBF is accurate.[35] Currently, the existing prehospital data are insufficient to recommend ketamine use in combative prehospital head-injured patients.

Severe head injury is the most common reason for helicopter transfers in trauma care. Although the decision to transport by helicopter should be made on a case-by-case basis, considerations for helicopter use from an accident scene include a long extrication time, ground transport of longer than 30 minutes to an appropriate ED and trauma care facility, two or more severely injured patients at a scene, and assistance in performing expedient lifesaving procedures, especially airway management. Several recent studies have supported that the use of helicopter emergency services improves outcomes in severely head-injured patients.[24,36-38]

Controversy exists regarding the benefits of out-of-hospital intubations in patients with severe and moderate head injuries. It is unclear whether field intubations truly improve neurologic outcome or survival. Unsuccessful attempts at field intubations may add to out-of-hospital time and increase the risk of aspiration or hypoxia.[39-41]

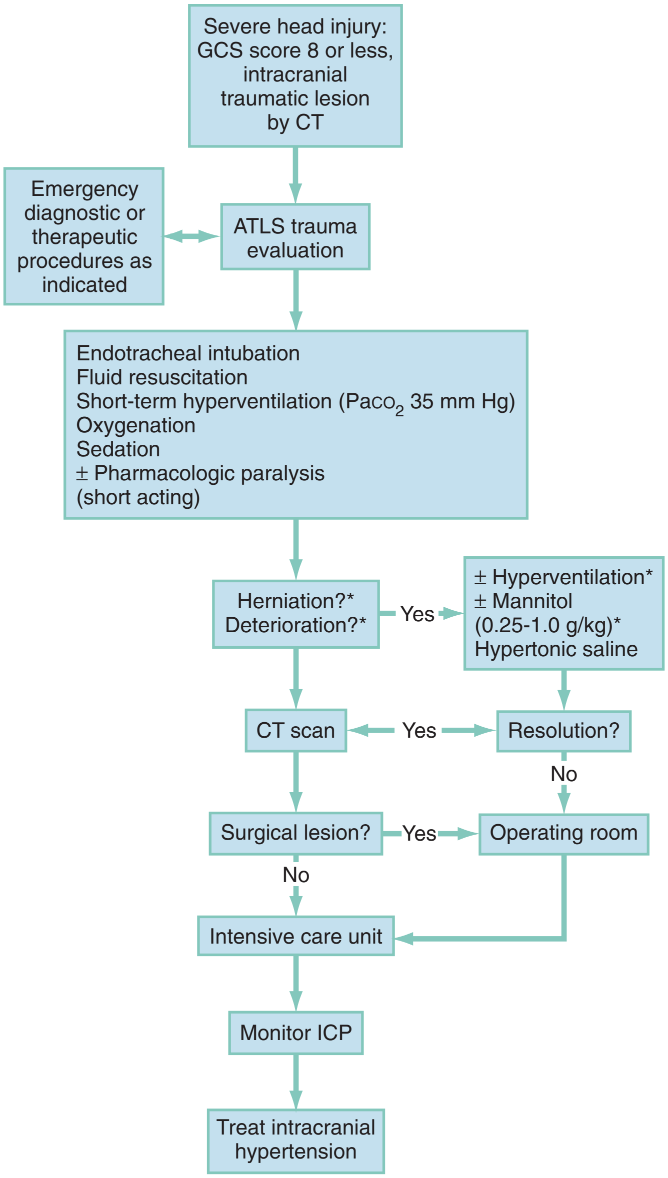
www.ketabpezeshki.com 66485457-66963820

In 1997 Winchell and Hoyt showed that patients who had sustained severe head injuries and who were intubated in the out-of-hospital setting had an improved survival compared with those who were not intubated.[29] Since that time, others have challenged this finding. In the San Diego paramedic rapid sequence intubation (RSI) trial, Davis and colleagues[42] found an increase in mortality and morbidity in patients who sustained severe head injuries and underwent out-of-hospital RSI compared with matched historical controls.[42] Potential explanations included frequent hypoxic episodes with associated bradycardia, unintentional hyperventilation, and prolonged scene times for those undergoing out-of-hospital RSI. Wang and colleagues found a fourfold increase in mortality among patients who sustained severe TBI and received ground ambulance intubation compared with ED intubation.[24] Flight clinician out-of-hospital intubation has been associated with decreased mortality and improved neurologic outcome, likely because of the higher airway management training requirements of air medical programs.[24,37-40] These studies are somewhat limited by lack of generalizability[24,42-46] (e.g., most emergency medical service systems do not have RSI capabilities) or by the use of nonvalidated outcome measures of neurologic function.[24] Out-of-hospital intubation carries the following risks: frequent hypoxic episodes during intubation attempts, with or without concurrent bradycardia; unintentional hyperventilation of intubated patients; prolonged scene times because of the time demands associated with the intubation process; and persistent hypotension, likely from other injuries that go unattended while the airway management occurs. However, hypoxia must be avoided in head-injured patients, and out-of-hospital airway protocols balance the risks of emergency intubation in an uncontrolled setting with the need to secure an airway at risk.

The key to a successful out-of-hospital RSI program involves well-trained clinicians with specific RSI protocols, involved medical control, frequent continuing education, and consistent quality assurance and improvement. Fakhry and colleagues[47] reported that their helicopter clinicians had a 96.6% RSI success rate with few complications and no esophageal intubations.

Emergency Department (Fig. 41-6)

Airway. RSI is the preferred method for securing the airway in combative or agitated patients. If possible, a brief neurologic examination should be performed before the patient is given any sedative or neuromuscular blocking agents. In general, the agents used for RSI in the head-injured patient are the same as those used for other patients, although attention is given to the increased ICP that can potentially occur with any physical stimulation of the respiratory tract. Lidocaine (1.5-2 mg/kg intravenous push) may attenuate the cough reflex, hypertensive response, and increased ICP associated with intubation, although this is vigorously debated.[47-49] If succinylcholine is used, premedication with a subparalytic dose of a nondepolarizing agent can be considered if time permits because fasciculations produced by succinylcholine may increase ICP. The degree of ICP elevation and its clinical significance are unclear, however, and are balanced against the need for rapid establishment of an airway. Etomidate (0.3 mg/kg intravenously [IV]), a short-acting sedative-hypnotic agent, has beneficial effects on ICP by reducing CBF and metabolism.[50] In addition, etomidate has minimal adverse effects on blood pressure and cardiac output and fewer respiratory depressant effects than other agents. Concern has been raised that single-dose etomidate used during RSI may adversely affect patient outcome by modulating the inflammatory response and transient adrenal suppression.[51] However, research both supporting and refuting this position exists, and no definitive answer has yet been established.[51-56]



*Only in the presence of signs of herniation or progressive neurologic deterioration not attributable to extracranial factors.

Figure 41-6. Initial resuscitation of patient with severe head injury: treatment options. *ATLS,* advanced trauma life support; *CT,* computed tomography; *GCS,* Glasgow Coma Scale; *ICP,* intracranial pressure; $Paco_2$, arterial carbon dioxide partial pressure. (From the Brain Trauma Foundation, American Association of Neurological Surgeons, Joint Section on Neurotrauma and Critical Care: Introduction. Guidelines for the management of severe traumatic brain injury. J Neurotrauma 17:465, 2000.)

Hypotension. Hypotension is rarely caused by head injury except as a terminal event. If hypotension is detected at any time in the emergent management of a head-injured patient, a cause other than the head injury should be sought. Some important exceptions occur. Profound blood loss from scalp lacerations can cause hypovolemic hypotension. In infants, hemorrhage into an epidural or subgaleal hematoma can produce profound hypovolemic shock. In the presence of a concomitant high spinal cord injury, neurogenic hypotension may occur. This is rare, and usually the cord injury is apparent on physical examination. In less obvious cases, neurogenic hypotension can be differentiated from hypovolemic hypotension by its nonresponsiveness to fluid

www.ketabpezeshki.com 66485457-66963820

administration and by the presence of inappropriate bradycardia in the face of hypotension.

Systemic hypotension cannot be tolerated in the head-injured patient without profound worsening of neurologic outcome; fluids or blood transfusion should therefore be delivered to maintain a systolic blood pressure of at least 90 mm Hg.[22] The delivery of large amounts of fluid to severely head-injured patients who are hypotensive from other injuries does not produce clinically significant increases in ICP; fluids should never be withheld in the head trauma patient with hypovolemic hypotension for fear of increasing cerebral edema and ICP. The resuscitation goal is to keep the CPP at 50 or above. Hypotension may interfere with the accurate neurologic assessment of the brain-injured patient. Often, when blood pressure is restored, an improved neurologic status is observed.

Traditionally, normal saline or lactated Ringer's solution has been used for resuscitation of trauma patients with hypovolemic hypotension. Some research suggests that fluid resuscitation with hypertonic saline (HTS) rather than normal saline may improve neurologic outcome after TBI. However, recent data from the Resuscitation Outcomes Consortium showed no improvement in neurologic outcome when HTS was administered in the prehospital setting in severely head-injured patients not in hemorrhagic shock.[57]

As many as 50% of patients with severe head injury are victims of multiple trauma.[22] The dramatic presentation of the head injury should not distract the clinician from a thorough search for other life threats.

The ED neurologic assessment should be compared with the initial out-of-hospital examination, with a focus on evidence of neurologic deterioration or signs of increasing ICP. If the patient is deteriorating or has signs of increased ICP, active intervention is initiated in the ED.

Hyperventilation. Acute hyperventilation is a lifesaving intervention that can prevent or delay herniation in the patient with severe TBI while more definitive resources are mobilized. The goal is to reduce the Pco_2 to the range of 30 to 35 mm Hg. Hyperventilation will reduce ICP by causing cerebral vasoconstriction; the onset of effect is within 30 seconds[23] and probably peaks within 8 minutes after the Pco_2 drops to the desired range. In most patients, hyperventilation lowers the ICP by 25%; if the patient does not rapidly respond, the prognosis for survival is generally poor.

Prolonged hyperventilation is not recommended because it may cause profound vasoconstriction and ischemia. This vasoconstriction worsens CBF that is already severely compromised during the first 24 hours after TBI.[12] Hyperventilation should be viewed as a short-term lifesaving intervention and should be used only when a patient experiences an acute neurologic decline or demonstrates signs consistent with herniation.

Osmotic Agents. Additional therapy for increased ICP includes the use of osmotic diuretics, such as mannitol and HTS. With deepening coma, pupil inequality, or other deterioration of the neurologic examination, osmotic agents may be lifesaving.

Mannitol is the mainstay for control of elevated ICP in acute severe TBI. The Brain Trauma Foundation and the European Brain Injury Consortium recommend mannitol as the osmotic drug of choice.[40,41] However, few comparative data exist on mannitol and other ICP-lowering medications.[58] A Cochrane database review concluded that mannitol may have a small beneficial effect compared with pentobarbital.[59] ICP-directed therapy based on neurologic signs may also be beneficial. However, other evidence suggests that mannitol may be detrimental compared with HTS.[59,60] Further research is needed on optimal osmotic therapy in severe head trauma.

Mannitol (0.25-1 g/kg) can effectively reduce cerebral edema by producing an osmotic gradient that prevents the movement of water from the vascular space into the cells during membrane pump failure and draws tissue water into the vascular space. This reduces brain volume and provides increased space for an expanding hematoma or brain swelling. The osmotic effects of mannitol occur within minutes and peak approximately 60 minutes after bolus administration. The ICP-lowering effects of a single bolus may last for 6 to 8 hours.[61] Mannitol has many other neuroprotective properties. It is an effective volume expander in the presence of hypovolemic hypotension and therefore may maintain systemic blood pressure required for adequate cerebral perfusion. It also promotes CBF by reducing blood viscosity and microcirculatory resistance. It is an effective free radical scavenger, reducing the concentration of oxygen free radicals that may promote cell membrane lipid peroxidation. However, mannitol can produce renal failure or hypotension if given in large doses. It may also induce a paradoxical effect of increased bleeding into a traumatic lesion by decompressing the tamponade effect of a hematoma. Because of these and other potential problems, the use of mannitol should be reserved for head-injured patients with evidence of increasing ICP and neurologic deterioration.[61]

HTS has been used for severe TBI since 1919.[62] Numerous clinical studies have demonstrated that HTS can significantly reduce ICP; however, the total number of enrolled patients in these trials is small.[58,59,62,63] The interpretation of these clinical studies is complicated by variation in protocols, HTS concentration, and administration. Potential adverse events associated with HTS include renal failure, central pontine myelinolysis, and rebound ICP elevation.[64]

Encouraging clinical data are available on hospitalized pediatric TBI patients treated with a continuous infusion of 3% normal saline for control of intracranial hypertension.[65,66] The clinical studies using HTS for acute field resuscitation of severe TBI have had conflicting results. Using a post hoc analysis of adult trauma data, Vassar and colleagues[67] and Wade and colleagues[68] showed beneficial effects of HTS on patients with severe TBI. However, Cooper and colleagues[69] found no benefit for out-of-hospital use of HTS in reducing elevated ICP and improving CPP compared with lactated Ringer's in hypotensive patients who had a head injury. As noted earlier, a large, multicenter, double-blinded, randomized, placebo-controlled clinical trial showed no improvement in neurologic outcome when HTS was administered in the prehospital setting in severely head-injured patients not in hemorrhagic shock.[57]

Barbiturates. Barbiturate therapy is occasionally used in severely head-injured patients to reduce cerebral metabolic demands of the injured brain tissue. Barbiturates also affect vascular tone and inhibit free radical–mediated cell membrane lipid peroxidation. The effects of barbiturates are delayed relative to other acute interventions for reducing ICP; therefore they are rarely initiated in the ED. If other methods of reducing ICP have been unsuccessful, barbiturates may be added in the hemodynamically stable patient. Pentobarbital is the barbiturate most often used.[70]

Steroids. Despite their popularity in the past, there is no benefit to giving steroids in head-injured patients. They do not lower ICP, and high-dose methylprednisolone in moderate and severe TBI is associated with increased mortality.[71]

Hypothermia. Although hypothermia remains a significant area of research and promise for patients with severe and moderate TBI, the available scientific evidence is inconclusive with regard to improved mortality or morbidity with prophylactic hypothermia in patients with severe and moderate TBI. In a meta-analysis performed by the Brain Trauma Foundation, duration of hypothermic treatment for more than 48 hours was associated with a reduction in mortality. This finding is significantly limited owing to small sample sizes.[72] A large trial of hypothermia use in moderate and severe TBI has recently begun in Europe. The Eurotherm3235 Trial will enroll 1800 patients over 41 months.[73]

www.ketabpezeshki.com 66485457-66963820

Cranial Decompression. Patients with signs of herniation who have not responded to other means of ICP reduction and who are rapidly deteriorating in the ED should be considered for placement of emergency burr holes. Emergency trephination has been described for centuries. It is a blind invasive procedure, and the chances of localizing the expanding lesions are uncertain. In patients who do not respond to hyperventilation and osmotic agents and have a unilateral dilated pupil with a history of "talk and deteriorate" after head trauma, emergency cranial decompression may temporarily reverse or arrest the herniation syndrome.[74-77] In this setting, emergency trephination may allow enough time for a patient to undergo a formal craniotomy in the operating room.

Most patients who have been unconscious since an accident occurred—with erratic or absent respiratory effort, bilateral fixed and dilated pupils, no spontaneous eye movements, and decerebrate posturing—have sustained diffuse massive brain injury with no focal lesion amenable to emergency decompression. These patients do not benefit from emergent burr holes. Instead, these patients should undergo rapid CT scanning or formal surgical decompression.

There has been renewed interest among neurosurgeons in the role of emergent decompressive craniectomy. Numerous papers have been published promoting more liberal use of decompressive craniectomy in patients with severe brain swelling and high ICPs.[21] Outcome measurements have not been consistent, and results have been mixed. If performed, the procedure should be done early in the patient's course. Two ongoing randomized studies may provide better direction regarding when this treatment is best indicated.[21]

Seizure Prophylaxis. Up to 12% of all patients who sustain blunt head trauma and 50% of those with penetrating head injury develop early post-traumatic seizures (PTSs).[78] Although the occurrence of seizures in the immediate post-trauma period has no predictive value for future epilepsy, early seizures can cause hypoxia, hypercarbia, release of excitatory neurotransmitters, and increased ICP, which can worsen secondary brain injury. Constantly firing neurons are soon depleted of their energy sources, and in the head trauma patient with compromised cerebral metabolism, uncontrolled seizures exacerbate the neurologic deficit.[23]

Box 41-2 lists accepted indications for early anticonvulsant therapy after head trauma. If the patient is actively seizing, benzodiazepines are administered as effective, rapid-acting first-line anticonvulsants. Lorazepam (0.05-0.1 mg/kg IV over 2-5 minutes up to a total of 4 mg) has been found to be most effective at aborting status epilepticus.[23] Diazepam (0.1 mg/kg, up to 5 mg IV, every 10 minutes up to a total of 20 mg) is an alternative. For long-term anticonvulsant activity, phenytoin (18-20 mg/kg IV) or fosphenytoin (15-18 phenytoin equivalents/kg) can be given. Fosphenytoin has the advantages of rapid administration, a smaller volume of fluid for the dose delivered, and less hypotension than phenytoin. In a Cochrane review, the use of antiepileptic drugs reduced the risk of early seizures by 66%.[79] Early seizure prophylaxis does not prevent late PTSs; the goal is to prevent additional insult to the damaged brain.[78-80]

If the patient has been paralyzed to facilitate management, clinical manifestations of generalized seizures are obscured. Therefore all paralyzed severely head-injured patients should receive prophylactic anticonvulsant therapy in the acute phase. Continuous electroencephalographic monitoring is necessary for the ongoing assessment of seizure activity in paralyzed patients and if available should be initiated in the ED or the intensive care unit.

Antibiotic Prophylaxis. Infection may occur as a complication of penetrating head injury, open skull fractures, and complicated scalp lacerations. Prophylactic antibiotics may be used in these circumstances but are not recommended in patients with only otorrhea or rhinorrhea from a basilar skull fracture.[81]

Recombinant factor VIIa (rFVIIa) is a hemostatic agent that was originally developed to treat bleeding in hemophiliacs. Considerable interest has arisen regarding its potential use in intracerebral hemorrhage.[82,83] rFVIIa costs approximately $1000/mg. Experience from the Iraq war and civilian use in multitrauma patients has produced conflicting results regarding its benefits in traumatic intracranial hemorrhage.[82-85] Use of rFVIIa for traumatic head bleeds should be individualized and undertaken in concert with an institution's treatment protocol. A recent review concluded that although off-label use of rFVIIa increased 140-fold from 2000 to 2008, no evidence exists that rFVIIa improves outcomes in five off-label indications. Specifically, the data regarding the use of rFVIIa in TBI are too limited for determination of the risks and benefits.[86] Head-injured patients taking anticoagulants who require an emergent craniotomy may benefit from rFVIIa administration because it decreases the time to operating room intervention.[82,83,85,86]

Ancillary Evaluation

Laboratory Tests. The acute management of the severely head-injured patient is directed by physical examination and diagnostic imaging. Ancillary laboratory tests that may provide useful information in the subsequent management of the patient include a urine toxicology screen, blood alcohol level, complete blood count, electrolytes, glucose, and coagulation studies.

Neuroimaging. In the acute phase the most useful imaging technique is a non–contrast-enhanced head CT scan. This scan delineates acute intra-axial and extra-axial bleeding, subarachnoid blood, cerebral swelling, ischemic infarction caused by hypoxia after trauma, evidence of increased ICP, and pneumocephalus. Emergency management decisions are strongly influenced by these acute CT scan findings. The bone windows of the CT scan can detect skull fractures (including basilar fractures); plain skull radiographs are not necessary in patients who undergo CT scanning.

Magnetic resonance imaging (MRI) is better than CT in detecting post-traumatic ischemic infarctions, subacute nonhemorrhagic lesions and contusions, axonal shear injury, and lesions in the brainstem or posterior fossa. Monitoring and managing patients in the MRI suite can be very difficult, especially patients with severe TBI who have other life-threatening injuries. MRI is not recommended as the first-line imaging modality for severe or moderate head injury.

Disposition

Consultation. All patients with severe head trauma require an imaging modality to determine the extent and nature of the brain injury and the necessity of neurosurgical intervention. Neurosurgical consultation should be obtained as soon as possible to help direct the patient's subsequent management.

Transfer. Severely head-injured patients require admission to an institution capable of intensive neurosurgical care and acute neurosurgical intervention. If this is not available at the receiving

Box 41-2 Indications for Acute Seizure Prophylaxis in Severe Head Trauma

- Depressed skull fracture
- Paralyzed and intubated patient
- Seizure at the time of injury
- Seizure at emergency department presentation
- Penetrating brain injury
- Severe head injury (Glasgow Coma Scale score 8 or lower)
- Acute subdural hematoma
- Acute epidural hematoma
- Acute intracranial hemorrhage
- Prior history of seizures

hospital, the patient should be transferred to an appropriate institution by the most expedient transport method available.

Priority Management. The hemodynamically unstable patient with multiple trauma that includes head injury presents difficult emergency management decisions. The emergency physician should decide on the sequence that best addresses the most life-threatening pathologic conditions while still preventing morbidity and mortality from other serious injury. If the patient requires immediate surgical intervention for a life-threatening chest or abdominal injury, complete evaluation of the head injury may be curtailed. Moreover, these patients are anesthetized for surgery, and any neurologic deterioration is not detected. Some patients may be too unstable for even an abbreviated head CT scan to be obtained before emergent surgical intervention for other life threats. In this circumstance, early neurosurgical and general surgical consultation should be coordinated by the emergency physician. Intraoperative ventriculostomies or bilateral trephinations may provide some temporary protection from increasing ICP while the patient undergoes surgical correction of the life-threatening injury. A CT scan is performed after the primary life threats have been corrected.

Moderate Head Trauma

Approximately 10% of all patients with head injury have sustained moderate TBI, defined as a postresuscitation GCS score of 9 to 13. Moderate TBI is often caused by MVCs. Most patients with moderate TBI do not die at the scene from their initial head injury and are brought to the ED for stabilization and evaluation.

Moderate TBI produces a number of physiologic abnormalities, including neuronal cell membrane dysfunction and a mild, brief acidosis with no concurrent depletion of adenosine triphosphate. These changes are probably reversible and therefore may be amenable to acute intervention to correct or prevent progression. The neuropathology of moderate brain injury probably represents the front end of the spectrum of pathophysiology seen with severe head trauma. Because of this, patients are vigilantly monitored to avoid hypoxia and hypotension and other secondary systemic insults that could worsen neurologic outcome.

Clinical Features and Acute Management

A wide variety of clinical presentations occur with moderate head injury. Patients often have experienced a change in consciousness at the time of injury, a progressive headache, PTSs, vomiting, and post-traumatic amnesia. On ED presentation, patients are often confused or somnolent, but most can still follow commands. Focal neurologic deficits may be present. Many patients with moderate head trauma have concurrent serious facial injuries that may interfere with attempts at securing their airway. Other systemic trauma should also be ruled out.

An important clinical scenario in the spectrum of moderate head injury is that of the talk and deteriorate patient. These patients have a GCS score of 13 or greater on presentation but deteriorate to a status of a severe head injury (GCS score 8) within 48 hours.[87] Although this description can include patients with minor head trauma, most patients who talk and deteriorate initially have GCS scores suggesting moderate head trauma. When the syndrome was first described by Reilly more than 30 years ago,[88] the mortality in head-injured patients who were talking at presentation was estimated to be as high as 38%.[87-90] However, CT scans were not readily available at that time, and the GCS was not in widespread use. With the current availability of early CT scanning, as well as rapid transport via emergency medical services, injuries are detected earlier, and the mortality of talk and deteriorate is lower—estimated to be 2.5 to 12%.[87,91] In early descriptions of talk and deteriorate, most patients were found to have sustained subdural or epidural hematomas (EDHs). More recently, an equal number have been found to have contusions with subsequent edema.[87,91] Patients who talk and deteriorate are generally elders with higher injury severity scores.[87,91,92] In addition, anticoagulation puts patients at increased risk.

Successful management of moderately head-injured patients involves close clinical observation for changing mental status or focal neurologic findings, early CT scanning, and aggressive neurosurgical intervention. When no neurosurgeon is available and the patient develops symptoms consistent with herniation syndrome not reversed by acute hyperventilation and mannitol, ED trephination and hematoma evacuation of any amenable lesion should be considered.

Because of the varied presentation of patients with moderate head trauma, the initial examination alone cannot accurately predict who will have surgically correctable intracranial lesions. Traumatic intracranial lesions are frequent in moderately head-injured patients. Even patients with a GCS score of 14 have a reported rate of 14% traumatic intracranial lesions.[21] A CT scan is essential in patients with moderate head trauma to avoid delayed diagnosis of traumatic mass lesions or diffuse injury. This is especially true for elders or patients on anticoagulation therapy.[93,94] Skull radiographs may be useful if the patient has sustained a depressed skull fracture or a penetrating injury but are otherwise rarely helpful.

Disposition

All patients with moderate head injury should be admitted for observation, even with an initial apparently normal CT scan. Most patients improve over the first few days after injury.[23] Frequent neurologic checks should be initiated, and a repeated CT scan is indicated if the patient's condition deteriorates or fails to improve over the first 48 hours after trauma.

Complications

The overall mortality of patients with isolated moderate TBI is approximately 20%, but the morbidity is substantial. Most patients with moderate TBI remain symptomatic for extended periods after head injury. At 3 months after trauma, up to 70% are unable to return to work, 90% have memory difficulties, and more than 90% complain of persistent headaches.[95-98] TBI increases long-term mortality. One research group found that with regard to life expectancy, on average, TBI shortens the life span compared with non-TBI patients.[99,100] Almost 50% are left with a long-term disability that interferes with their previous daily activities.[98] In patients with persistent symptoms of headache, confusion, or memory difficulties, delayed MRI may define lesions in the regions related to cognition that cannot be seen on CT. Although not useful in the acute setting, MRI has prognostic value during subsequent care and assists in directing the future rehabilitation of these patients.

Minor Head Trauma

Minor or minor head trauma (MHT) is an injury to the brain resulting in a temporary and brief interruption of neurologic function after head trauma, which may involve a loss of consciousness (LOC).[56,101] The neuropathology involved in producing signs and symptoms of minor TBI may remain at the neurobiochemical level without damage to the microstructure. Heightened ionic flux, surges in levels of glutamate transmitters, disruption of enzymatic pathways, and accumulation of lactate and nitric oxide have

www.ketabpezeshki.com 66485457-66963820

been reported in brain tissue after experimental minor TBI.[17] Axonal stretching or twisting may occur with some mechanisms producing minor TBI. This injury pattern may promote glutamine-induced neurotoxic cascades that lead to the axonal damage typically described as DAI.[102] Experimental models of blast injury also produce these same changes.[103]

Most authorities, clinical policies, and decision rules now classify minor TBI as that producing a GCS score of 14 or 15.[17,101,102,104-106] In fact, the GCS is not sensitive enough to be of prognostic usefulness in minor TBI; a perfect score of 15 in the ED does not take into account the level of alertness or neurologic status immediately after trauma or the presence or absence of focal neurologic injury.[31,102,107]

From a practical standpoint, minor TBI is a clinical diagnosis. The diagnosis requires a credible mechanism of injury. In civilian life, most mechanisms that do not involve direct craniofacial impact cannot produce minor TBI. For example, belted drivers in low-velocity rear end–impact MVCs are not subjected to high enough acceleration-deceleration or rotary forces to the head to reach the force threshold needed to produce cerebral injury unless there is also direct impact to the head against a stationary object.[102,108] It is therefore unlikely that a patient with a whiplash or "jolt" injury would also have minor TBI. Collision sports–related minor TBI can be caused by acceleration-deceleration. Although the extent of this mechanism is not yet known, forces generated in blast injuries in wounded service personnel are the most common cause of minor TBI without direct head impact. Mild TBIs from blast injuries have been called the signature injury of the wars in Iraq and Afghanistan.[103]

Clinical and Historical Features

By the time most patients with minor TBI reach the ED, their symptoms are resolving or have completely resolved. The most common complaint after minor TBI is headache. Other common problems are nausea and emesis. Patients may also report transient disorientation, confusion, or amnesia. There is little evidence to correlate these symptoms with the presence of intracranial lesions in patients with minor TBI.

Clinical signs and symptoms of minor TBI include balance deficits, impaired verbal memory, delayed language comprehension, slowed speech, amnesia regarding the impact, a period of disordered awareness (with or without LOC), and a finite period of post-trauma amnesia (PTA).[91,102,108] Retrograde amnesia is impaired information retrieval and begins with and includes the traumatic event. In minor TBI, it generally lasts up to several minutes and then very rapidly resolves. PTA is impairment of information encoding and therefore does not resolve. PTA is the period of time from the injury to the return of conscious recall: events during this interval are essentially lost to the patient. PTA is a better predictor of injury severity and eventual outcome than the duration of retrograde amnesia or the GCS score.[102]

Approximately 5 to 15% of patients with minor TBI in the ED with a GCS score of 15 have abnormal CT scans.[102,104,109] This estimate is probably inflated, because at least 25% of patients with minor TBI never seek medical care. The incidence of life-threatening lesions that require neurosurgical intervention after minor TBI is variably reported but likely less than 1%[104]; the goal of emergency evaluation and management of patients with minor TBI is to identify these high-risk patients. Further diagnostic workup hinges on risk stratification in patients with minor TBI (Box 41-3). The criteria are based on several large studies, but because of inconsistent methodology and reporting, they have limitations. For example, LOC in minor head trauma has historically been considered a risk factor for significant injury, but the negative predictive value of LOC has not been determined, and many patients with minor TBI may have sustained only brief or no LOC.[110,111] Animal studies and anecdotal reports on humans suggest that the longer the duration of LOC, the more likely that an intracranial lesion exists, but the actual correlation between the duration of the LOC and the incidence of intracranial lesions or injury severity has not been determined.[108-112] Other high-risk minor head trauma criteria have also been proposed. The key for the emergency physician, however, is to determine the low-risk patient, and these criteria are less controversial.

Box 41-3 Risk Stratification in Patients with Minor Head Trauma

High Risk
Focal neurologic findings
Asymmetrical pupils
Skull fracture on clinical examination
Multiple trauma
Serious, painful, distracting injuries
External signs of trauma above the clavicles
Initial Glasgow Coma Scale score of 14 or 15
Loss of consciousness
Post-traumatic confusion or amnesia
Progressively worsening headache
Vomiting
Post-traumatic seizure
History of bleeding disorder or anticoagulation
Recent ingestion of intoxicants
Unreliable or unknown history of injury
Previous neurologic diagnosis
Previous epilepsy
Suspected child abuse
Age above 60 years or below 2 years

Medium Risk
Initial Glasgow Coma Scale score of 15
Brief loss of consciousness
Post-traumatic amnesia
Vomiting
Headache
Intoxication

Low Risk
Currently asymptomatic
No other injuries
No focality on examination
Normal pupils
No change in consciousness
Intact orientation and memory
Initial Glasgow Coma Scale score of 15
Accurate history
Trivial mechanism
Injury less than 24 hours ago
No or mild headache
No vomiting
No preexisting high-risk factors

Imaging Studies

A major decision regarding the emergency management of minor TBI is whether imaging studies should be performed. Several approaches have recently been described, but the research behind these suggestions remains confusing primarily because of differences in study populations, definitions, methods, risk factors included in analysis, and selection of acceptable outcomes. Based on critical assessment of the literature designed to address this question, the American College of Emergency Physicians (ACEP) has developed a clinical policy on neuroimaging of adult ED patients with mild TBI.[104] The recommendations from the ACEP clinical policy are summarized in Box 41-4.

www.ketabpezeshki.com 66485457-66963820

Box 41-4 American College of Emergency Physicians Clinical Policy Regarding Neuroimaging in Adults with Mild Traumatic Brain Injury

A noncontrast head CT is indicated (level one recommendation) in adults with LOC or post-traumatic amnesia only if one or more of the following is present:

- Headache
- Vomiting
- Age older than 60 years
- Drug or alcohol intoxication
- Deficits in short-term memory
- Physical evidence of trauma above the clavicle
- Post-traumatic seizure
- GCS score below 15
- Focal neurologic deficit
- Coagulopathy

A noncontrast head CT should be considered (level two recommendation) in head trauma patients with no LOC or post-traumatic amnesia if there is:

- Focal neurologic deficit
- Vomiting
- Severe headache
- Age 65 years or older
- Physical signs of a basilar skull fracture
- GCS score below 15
- Coagulopathy
- A dangerous mechanism (e.g., ejection from motor vehicle, pedestrian struck, fall of more than 3 feet or 5 stairs)

CT, computed tomography; *GCS*, Glasgow Coma Scale; *LOC*, loss of consciousness.

A critical comparison of six common decision-making strategies for neuroimaging in mild TBI has been made.[113] Although there are differences in the number of scans performed if each of the rules were applied to the same population, the sensitivity in detection of surgically important hematomas was not different among the rules. The final choice of which clinical decision rule to apply, and therefore the level of acceptable risk, rests on the clinician's attitude toward uncertainty.

The most practical approach regarding imaging in the ED patient is probably selective CT scanning or observation based on risk stratification of the patient with minor TBI. If the low-risk patient is fully awake and not intoxicated, has no focal neurologic findings, has no clinical evidence of skull fracture, and can be kept under competent observation for 12 to 24 hours, neuroimaging is usually not indicated. Patients with moderate-risk minor head trauma (see Box 41-3) should probably undergo CT scanning or prolonged ED observation.

Skull radiography after head trauma in adults has been largely replaced by more sophisticated imaging when imaging is performed. Patients with clinical signs of skull fracture have a substantially increased incidence of intracranial lesions associated with their minor head trauma. When the clinical examination shows evidence of skull fractures, CT scanning should be performed and plain radiographs should be forgone.

Although CT scanning is extremely sensitive for acute blood, MRI is more sensitive than CT for detecting DAI, ischemia after TBI, and some hemorrhagic lesions, especially those located at the base of the skull or in the posterior fossa.[114,115] However, there is no current evidence favoring the use of MRI over CT for MHT in the ED setting.[104] Many studies suggest that significant long-term neuropsychiatric sequelae after minor head trauma can occur despite an initial negative head CT scan, and these may be related to lesions seen initially only through MRI or functional imaging.[116] Functional imaging is not currently within the scope of emergency assessment of patients with minor TBI but can direct rehabilitation strategies for the small subset of patients with significant morbidity after minor TBI.

Ancillary Studies

No routine laboratory tests are needed for patients with isolated minor head trauma. A urine toxicology screen and blood alcohol level may be useful in interpreting the patient's mental status. Alcohol can affect the GCS, but this effect is not observed until the blood alcohol concentration is greater than 200 mg/dL; until that level, changes in mental status cannot be explained solely by acute alcohol intoxication.[102]

When shear injury occurs, proteins are released from neuronal axons. These proteins cross the BBB and can be detected in the peripheral circulation. A number of CNS biomarkers, such as S-100B, neuron-specific enolase, myelin basic protein, cleaved tau, and creatine kinase isoenzyme BB, have been investigated in minor TBI. None have been shown to strongly correlate with long-term outcome, and only S-100B predicts abnormal CT findings in minor TBI if measured within 4 hours of injury.[18] However, S-100B appears to lack CNS specificity and is found in adipose, skin, and cartilage; it is therefore often elevated in multiple-trauma patients with no head injury.[117] To date, serum biomarkers have lacked the precision needed for meaningful application in the emergency setting.[118]

Disposition

Most patients with low-risk minor TBI can be discharged from the ED with normal examination findings and after a reasonable period of ED observation (i.e., 4 to 6 hours). If the emergency physician decides that the patient with moderate- or high-risk minor TBI can be sent home, an appropriate early follow-up should be arranged. Patients should be discharged with instructions describing the signs and symptoms of delayed complications of head injury, should have access to a telephone, and should be monitored in the acute post-trauma period by a responsible, sober adult. If any doubt exists regarding the safety of the discharged patient with minor head injury, a brief inpatient observation period (i.e., 12 to 24 hours) is advisable.

If resources allow, prolonged ED observation may be practical in some circumstances. For example, intoxicated patients with minor TBI who otherwise fulfill low-risk criteria should undergo meticulous serial evaluations in the ED until clinical sobriety is achieved. In these patients, a CT scan may be unnecessary, and ED observation is beneficial.

If a patient with minor head trauma returns to the ED because of persistent symptoms, delayed complications of minor head injury should be sought. If a CT scan was not initially performed, the intensity of symptoms may guide the decision to obtain a CT scan at the second visit. If a negative scan was initially obtained, the likelihood of the subsequent development of an intracranial lesion is small.[104] The decision to rescan is more complex in patients from certain subgroups who may be considered more likely to develop delayed complications. These include patients on anticoagulation, those with preexisting neurologic injuries that may obscure an examination, and those with previous neurosurgical procedures (such as ventriculoperitoneal [VP] shunts). The literature about repeat CT scanning in mild traumatic brain injury (MTBI) is scant; however, in one systematic review of severe and moderate TBI, progression of lesions most commonly correlated with overall injury severity and the patients' use of anticoagulants.[119]

Patients on Anticoagulation. All current minor head injury decision-making rules exclude patients who are taking Coumadin or antiplatelet medications. Most current practice guidelines promote that patients who sustain head trauma and are on anticoagulation treatment should have the international normalized ratio (INR) determined and should undergo a CT scan without contrast.

www.ketabpezeshki.com 66485457-66963820

Concussion. Almost all patients with minor TBI will have rapid and complete resolution of their symptoms. However, a subset of patients with mild TBI report symptoms that persist for long periods after trauma. A concussion (or complicated minor TBI) is a type of minor TBI usually caused by acceleration-deceleration or rotational injury to a freely mobile head and is most commonly associated with collision sports.[101,120] It is a complex pathophysiologic state resulting in short-lived distortion of axons, vasculature, and brain neuroanatomy. As with other types of minor TBI, acute CT or MRI abnormalities are not usually found[108,120] but functional imaging (i.e., positron emission tomography [PET]) reveals abnormalities with glucose uptake and blood flow.[116] Levels of neurotransmitters remain elevated, and a hypermetabolic state may persist in the brain for several days to weeks after the initial injury. This period is vulnerable to cumulative dysfunction if a second injury occurs, especially in children.[121]

The persistent symptoms after MHT are called the *postconcussive syndrome* (PCS) and generally include the domains of cognitive, psychomotor, and behavioral performance. The severity and duration of postconcussive symptoms may correlate with the abnormalities found with early functional imaging.[116,120] The incidence of PCS after MHT is reported to be 10 to 58% at 1 month after injury,[122] but these estimates are based on inpatient studies and are therefore likely to be high.

The most common delayed or persistent postconcussive complaints are headache, sensory sensitivity, memory or concentration difficulties, irritability, sleep disturbances, dizziness, depression, and amnesia regarding the traumatic event. In young children, acute symptoms of concussion differ from those in adults and may include restlessness, lethargy, confusion, or irritability.[120] The appearance of symptoms may occur long after the concussion, and they persist long after the acute symptoms of uncomplicated MHT.[120] It was once believed that persistent postconcussive symptoms were psychosomatic, litigious, or factitious; however, the presence of abnormalities on functional imaging and with sophisticated neuropsychometric testing suggests a pathophysiologic basis for PCS.[17,122] Studies of concussed athletes (for whom preinjury baseline data are available) show that the cognitive domain most frequently involved in PCS is memory.[17] Dizziness, headache, and nausea occurring early after trauma are associated with prolonged PCS; patients with all three symptoms have a 50% chance of persistent symptoms at 6 months, compared with a 28% chance for those with MHT with none of these symptoms at presentation.[122] Most adult patients with PCS recover within 3 to 12 months after injury.[100,104,115,120]

Approximately 300,000 sports-related concussions occur annually each year. Among these, about 135,000 are in child athletes aged 5 to 18 years.[123] A study of concussed football players showed acute symptoms lasting at least 5 days, cognitive impairments lasting 5 to 7 days, and balance deficits lasting 3 to 5 days after concussion; 91% were back to their preinjury baseline by 7 days, but some had deficits on verbal fluency tests as long as 90 days after injury.[124] As a result of these and other data, educational campaigns have been launched for athletes on the signs and symptoms of concussion and steps to take when a concussion has occurred during play. The CDC has developed a number of "Heads Up" tool kits aimed at players, parents, and coaches to address these goals.[123] The CDC, National Football League (NFL), NFL Players Association, Professional Football Athletic Trainers Society, and NFL Physician's Society initiated a joint effort in 2010 with similar aims.

The demonstrated period of neurodysfunction and the delayed return to cognitive and physical baseline that follows concussive impact have lead to the development of several scoring systems to grade severity of concussions with the goal of determining when it is safe for an athlete to return to play. No single set of guidelines has emerged that has been universally accepted, but all are predicated on the concern about a period of vulnerability after impact. Football players sustaining concussion appear susceptible to an additional concussion, with the majority of reinjury occurring within 10 days after the first injury. This is variably attributed to balance defects, delayed reflexes, delayed speed of information processing, or simply continued exposure to collision sports.[123] Recent consensus of sports medicine experts emphasizes physical and cognitive rest after sports-related concussion until complete symptom resolution.[123,125] Although some organizations have published guidelines for rapid return to play (RTP) after a concussion (including same-day return), most are applicable only to professional or elite athletes and only when adequate sideline resources are available to detect subtle symptoms (e.g., on-site sports doctors, formal sideline neuropsychometric testing). For high school and collegiate athletes, a stepwise strategy has been developed to clear the athlete for RTP[107] (Table 41-3). Progression from one step to the next requires that the athlete be asymptomatic; if symptoms recur, the patient drops back one step in the progression. This graduated RTP protocol cannot be achieved without referral and long-term care; in the ED management of concussed athletes, no RTP should be allowed until such follow-up and progress have occurred. The second impact syndrome (SIS) occurs when an athlete sustains a second concussion before being completely asymptomatic from the first and then experiences a rapid, usually fatal, neurologic decline. It is postulated that persistent neurochemical disruptions and altered autoregulatory mechanisms after a first injury make the brain particularly vulnerable to marked brain swelling and subsequent herniation after a seemingly minor second impact. Although the existence and frequency of the SIS are controversial and hotly debated in the sports medicine literature, its serious implications affect subsequent management decisions regarding head-injured athletes and others with concussion.[126] All current recommendations for RTP after a sports-related concussion, including the graduated RTP protocol described earlier, state that players with concussion should not return to play for at least 1 week after they have become asymptomatic.

Table 41-3 Graduated Return-to-Play Protocol

REHABILITATION STAGE	FUNCTIONAL EXERCISE AT EACH STAGE OF REHABILITATION	OBJECTIVE OF EACH STAGE
1. No activity	Complete physical and cognitive rest	Recovery
2. Light aerobic exercise	Walking, swimming, or stationary cycling, keep intensity to <70% of maximum predicted heart rate; no resistance training	Increase heart rate
3. Sport-specific exercise	Skating drills in ice hockey, running drills in soccer; no head impact activities	Add movement
4. Noncontact training drills	Progression to more complex training drills, for example, passing drills in football and ice hockey; may start progressive resistance training	Exercise, coordination, and cognitive load
5. Full-contact practice	With medical clearance, participate in normal training activities	Restore athlete's confidence; coaching staff assesses functional skills
6. Return to play	Normal game play

PEDIATRIC HEAD INJURIES

Epidemiology

Approximately 650,000 to 1 million children are emergently evaluated yearly in the United States for head trauma, with 80 to 90% classified as mild.[127,128] However, TBI accounts for the largest source of childhood mortality and morbidity after trauma. The etiology of TBI is age related; in infants and the very young, abusive injury is a major cause of TBI. In toddlers, abusive injury must be considered, but injury from falls appears more common. Once children enter school, injuries from physical activities (such as bicycle riding) and MVCs (especially pedestrians stuck by cars) are the most common causes of TBI.[129-131]

Pathophysiology

Until the cranial sutures close, children's skulls are more distensible than those of adults. As a result, young children often sustain less TBI after head trauma than adults with comparable nonfatal mechanisms of injury.[132] However, children appear to have an age-dependent brain vulnerability. Very young children (younger than 1 year) have higher mortality after head trauma than older children with injuries with the same severity of injury. Many factors contribute to this. Medical attention is often delayed in children with nonaccidental injuries. Because of limited language and comprehension, an accurate formal neurologic examination in young children is sometimes difficult. Medical personnel tend to underestimate the extent of the injuries in small children and are often reluctant to initiate invasive procedures that may be necessary to aid in the diagnostic workup, such as intravenous access for sedation in CT scanning.

The types of TBI sustained after head trauma in children differ from those in adults. Children have fewer traumatic mass lesions (with the exception of SDHs in the very young), fewer hemorrhagic contusions, more diffuse brain swelling, and more diffuse axonal injury. Of head-injured patients younger than 20 years who talk and deteriorate, 39% have brain swelling only (i.e., no mass lesions), whereas 87% of patients older than 40 who talk and deteriorate have mass lesions.[89]

Clinical Features

As with adults, an accurate description of the mechanism of injury, the appearance of the child immediately before and after the injury, and subsequent events can provide useful information to assist in the evaluation and management of the acutely head-injured child.

The initial physical presentation of a child with TBI may have minimal predictive value in terms of the severity of trauma sustained.[133] Therefore repeated examinations to detect changes in the neurologic status are paramount.

In principle, the acute neurologic assessment of head-injured children is the same as that of adults. Because of its reliance on developed language skills and the patient's attention and cooperation, the GCS is difficult to apply to very young children. A modified scale (see Table 38-4) has been developed[134] and has been shown to accurately predict the need for neurosurgical intervention in head-injured preverbal children.[135]

Children with severe or moderate head injury are clinically similar to adults with these degrees of injury, although children have an increased incidence of early (i.e., within the first week after trauma) PTSs after severe head injury.[23] Low GCS score and young age are associated with an increased early PTS risk. Even after adjustment for GCS score, children younger than 2 years have up to a threefold increased risk compared with older (i.e., older than 12 years) children.[66] Overall, up to 6% of all head-injured children and 20% of severely head-injured children have early PTS. Most PTSs occur within the first 24 hours and do not predict seizures later in the post-traumatic period. However, early PTS can exacerbate secondary brain injury by creating hypoxia and increasing cerebral metabolism and ICP. Although prophylactic use of anticonvulsants is not recommended to prevent late PTSs, acute anticonvulsant prophylaxis is a treatment option in severely head-injured infants and young children to prevent early PTSs.[66]

The clinical presentation of post-traumatic *intracranial lesions* in infants who have sustained moderate or severe TBI can be extremely subtle, especially in those younger than age 6 months. Often these lesions are associated with scalp injuries and skull fractures but no other symptoms. Toddlers are also difficult to assess; the only symptom of an intracranial injury may be irritability.[138,139] Recommendations are also offered regarding the ED workup in these very young children.

Inflicted head injury, also described as *abusive head injury* or *nonaccidental head injury,* is the most common cause of head injury deaths in infants. Child abuse is considered in all children with unexplained head injuries or injuries not consistent with the history provided. The *shaken baby syndrome* is most often seen in children younger than 1 year and is inflicted by violently shaking an infant while holding him or her by the torso or extremities. The uncontrolled head movement causes an acceleration-deceleration brain injury, with a rotary component, as the moving brain strikes against the interior of the skull. The resultant shearing injury causes widespread damage. Patients have a broad range of symptoms, from nonspecific complaints such as vomiting or sleepiness, to seizures and coma. Classically described findings include SDHs, and subarachnoid hemorrhage (SAH) without signs of external trauma. Diffuse retinal hemorrhages are seen in 50 to 100% of all patients with shaken baby syndrome; the extent of hemorrhage appears related to injury severity and may predict the prognosis.[130]

Children who sustain minor head trauma often have more pronounced physical signs and symptoms than adults. Despite apparently trivial trauma, children may appear pale, be lethargic, and have frequent emesis and complaints of headaches and dizziness.

Children with concussions tend to be symptomatic longer after mild TBI than adults. As in adults, postconcussive symptoms in children include neurocognitive changes. The severity and duration of postconcussive symptoms is related to the severity of initial injury, as well as personal and environmental factors. Children who have sustained LOC, post-traumatic amnesia, a GCS score less than 15 at presentation, or mental status changes are more likely to have prolonged postconcussive symptoms.[140,141] Thus children should not return to sports or play activities until completely symptom free, and then only at the discretion of their primary physician.[120] Concussive injuries in children also produce two unique clinical circumstances. Many children experience a brief *impact seizure* at the time of relatively minor head injury. By the time the child is evaluated, he or she is at baseline neurologic function. Impact seizures do not appear to predict subsequent early PTSs. However, a post-traumatic impact seizure may confuse the initial assessment of the severity of the head injury and prompt a more aggressive workup than needed. *Postconcussive blindness,* another serious complication of concussive injuries in children, is usually associated with impact to the back of the head. Children experience a temporary loss of vision that can persist from minutes to hours before normal vision returns.

Diagnosis and Management

As with adults, pediatric head-injured patients should be assessed for other major trauma and assumed to have cervical spine injury until proved otherwise. Goals of ED management are also

www.ketabpezeshki.com 66485457-66963820

generally the same: to prevent secondary injury and systemic insults, to prevent increasing ICP, and to detect traumatic mass lesions requiring emergency surgery.

Children with severe TBI who are transported directly to a pediatric trauma center or an adult trauma center with pediatric capabilities have better outcomes than those transported to non-trauma hospitals.[66] Hypoxia and hypoventilation are common in pediatric head-injured patients, and they develop more rapidly in children than in adults. In children with a GCS score below 8, airway management should be aggressive to prevent hypoxia, aspiration, and hypercarbia and to allow mild hyperventilation if the patient has signs of herniation. There is no evidence to support the advantage of out-of-hospital intubation over bag-valve-mask ventilation of pediatric patients with TBI[66,142]; scene time should not be prolonged with multiple attempts at endotracheal intubation.

Hypotension is a late finding in children in shock; poor perfusion should be clinically identified and corrected as soon as possible to ensure adequate CPP. There is no evidence to suggest that aggressive fluid resuscitation exacerbates cerebral edema in head-injured children. In children, unlike in adults, hypovolemic hypotension can occur because of head trauma. Hypotension from intracranial bleeding can occur in children younger than 1 year with a large linear skull fracture and an underlying large EDH.[132] The intracranial blood can seep through the fracture and produce a large galeal or subperiosteal hematoma. Hypotension from intracranial bleeding can also occur in a child with hydrocephalus and a functioning shunt. Blood may accumulate without much evidence of increased ICP. Scalp lacerations can also produce significant hemorrhage and subsequent hypotension.

Up to 80% of children with severe head trauma have elevated ICP.[132] In infants, a bulging fontanel suggests elevated ICP. Other signs of elevated ICP include bradycardia, papilledema, declining level of consciousness, and seizures. When increased ICP is indicated by physical examination, methods to reduce ICP should be initiated. As with adults, acute hyperventilation has immediate effects but is never indicated for prophylaxis or for prolonged management of increased ICP.[66] Hyperosmolar therapy is effective at reducing ICP. There have been no studies describing the superiority of one osmotic agent over another in the treatment of TBI, and no direct comparisons have been done. Although efficacy studies were based only on adults, mannitol at doses of 0.25 to 1.0 g/kg has become a mainstay in the treatment of elevated ICP in children with severe TBI. Bolus therapy has a theoretic benefit compared with continuous treatment; over prolonged periods, mannitol may accumulate in injured areas of the brain where the BBB is no longer intact, thus creating a reverse osmotic shift.[143,144] Several studies support the effectiveness of HTS in lieu of mannitol for elevated ICP in pediatric head-injured patients. Treatment is with a continuous infusion of 3% normal saline at 0.1 to 1.0 mL/kg body weight per hour, titrated to effect.[66]

Severely head-injured children are less likely to have a surgically amenable lesion than adults. Because diffuse brain swelling is the most common finding in severely head-injured children, emergency burr holes are generally ineffective.

When minor head injury is considered in children, age is an important consideration in interpreting clinical and historical findings. Children younger than age 2 years are often difficult to assess and may have subtle clinical findings. In general, the literature supports the conclusion that younger patients are at higher risk for intracranial injury. One clinical sign of potential brain injury in children younger than age 2 years is the presence of a scalp hematoma, especially a large parietal scalp hematoma.[143-145] In an observational cohort study involving children with low risk for brain injuries, scalp hematomas were present in 93% of children 2 years old or younger who had brain injuries.[144]

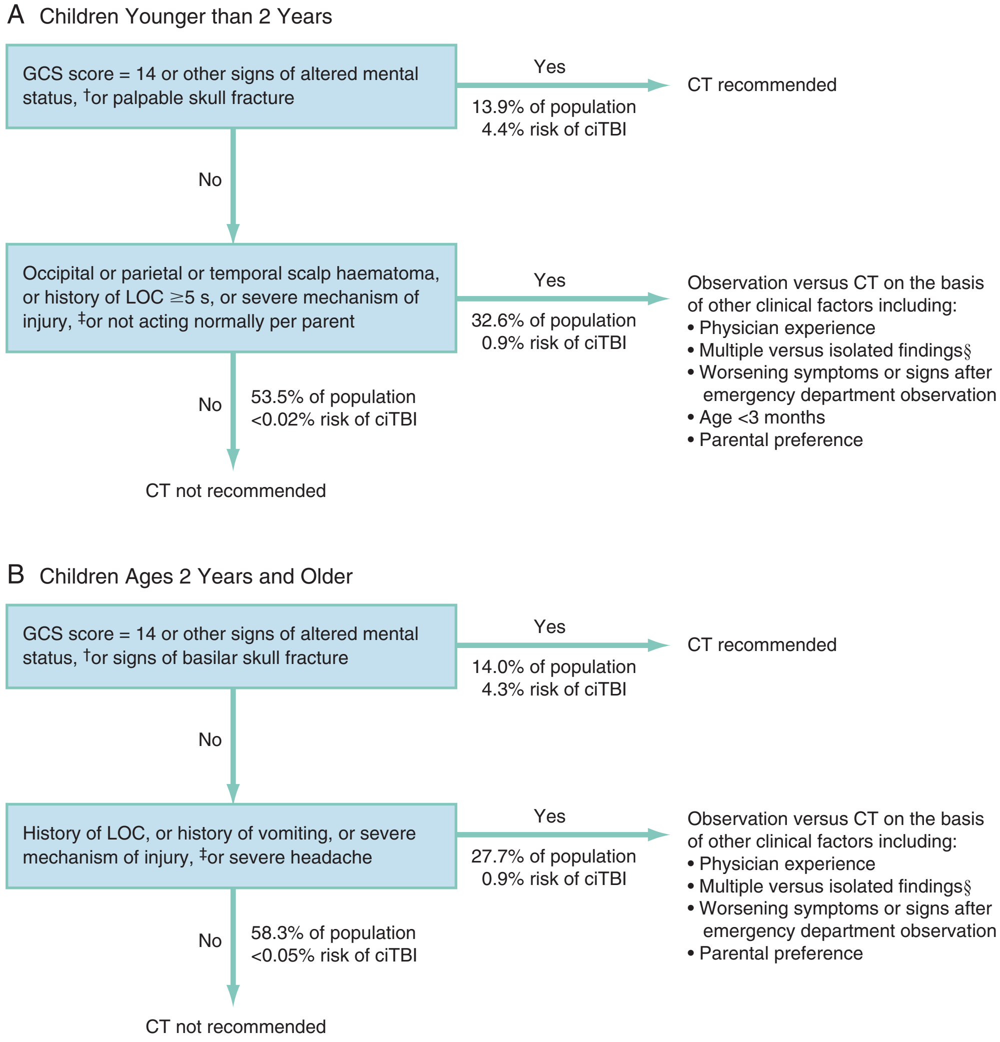
More than 50% of children with head injury of all severities in the United States undergo emergent cranial CT scanning.[127,146] Cranial CT is the diagnostic imaging modality of choice in the evaluation of moderate or severe pediatric TBI and should also be strongly considered in pediatric patients with high-risk minor TBI. However, potential risks are associated with childhood exposure to radiation. Children are more sensitive to radiation than adults because of rapidly dividing cells during normal growth. The younger the child, the more potential risk. Increased rates of solid tumor cancers[146] and decreased cognitive performance have been associated with radiation doses similar to that of a single head CT scan.[147] An additional safety concern is the frequent need to sedate young children in order to perform an adequate imaging study. In these circumstances, the risks of radiation exposure and sedation should be weighed against the likelihood of an intracranial lesion in the child with minor head trauma.

It is estimated that up to 98% of cranial CT scans done to assess head injury in children are negative.[145,148] Several clinical prediction rules have been developed to assist in decision-making for emergent neuroimaging of children with minor TBI. Comparison of these various rules is difficult because of variable methods and inclusion criteria. Most have not been validated in a separate population.[148,149] Unless both sensitivity and specificity are high, such rules may actually result in an increased number of CT scans being performed. Kupperman and colleagues,[145] with a research network including 25 EDs and 4200 patients, have derived and validated a clinical prediction rule for minor head trauma that includes subsets of children younger than 2 years and from 2 to 18 years old. The rule performs well with a very low risk of missed clinically important TBI in both age subgroups. An algorithm suggested by this study is presented in Figure 41-7. The CATCH study derived a decision rule that identified two levels of risk for children with minor head injury.[150] The large cohort of 3800 patients was identified from 10 Canadian pediatric teaching institutions. Children with a GCS score below 15 at 2 hours after trauma, a suspected open or depressed skull fracture, a worsening headache, or persistent irritability were found to be at increased risk for the need for a neurosurgical intervention and considered high risk; moderate risk (brain injury on CT with no need for neurosurgical intervention) was associated with any sign of basal skull fracture, a large boggy scalp hematoma, or a dangerous mechanism of injury (e.g., MVC or fall greater than 3 feet).

The use of skull radiographs in the diagnostic workup of head-injured children is controversial but may be appropriate in some circumstances. As with adults, when a CT scan is indicated, skull radiographs are not necessary. Up to 11% of children younger than age 2 years will sustain a skull fracture associated with head trauma, and 15 to 30% of these will have TBI. Therefore in children younger than age 2 years, a skull fracture is a predictor of TBI.[151] The presence of a skull fracture in children significantly increases the likelihood of intracranial pathology; conversely, a negative radiographic skull screen does not guarantee the absence of TBI. Parietal skull fractures are the most common. Often, fractures occur in infants who sustain relatively minor head injury. Skull films may be useful as a screening tool in determining the need for a CT scan, especially in children 2 years old or younger whose neurologic examination is difficult to obtain and interpret. In alert children younger than age 2 years with minor head injury, a low-risk history, normal findings on physical examination that includes a neurologic and mental status examination appropriate for age, and a scalp hematoma, skull radiographs may be a useful screen.[139] If the skull radiograph is negative for a fracture, a CT scan may be unnecessary. If the skull radiograph shows a fracture, CT imaging is indicated.

In older children, skull radiographs are rarely useful unless a specific lesion is suspected, such as a depressed skull fracture or a

www.ketabpezeshki.com 66485457-66963820



GCS = Glasgow Coma Scale. ciTBI = clinically important traumatic brain injury. LOC = loss of consciousness. Data are from the combined derivation and validation populations. †Other signs of altered mental status: agitation, somnolence, repetitive questioning, or slow response to verbal communication. ‡Severe mechanism of injury: motor vehicle crash with patient ejection, death of another passenger, or rollover; pedestrian or bicyclist without helmet struck by a motorized vehicle; falls of more than 0·9 m (3 feet) (or more than 1·5 m [5 feet] for panel B); or head struck by a high-impact object. §Patients with certain isolated findings (i.e., with no other findings suggestive of traumatic brain injury), such as isolated LOC,[39,40] isolated headache,[41] isolated vomiting,[41] and certain types of isolated scalp hematomas in infants older than 3 months,[31,42] have a risk of ciTBI substantially lower than 1%. Risk of ciTBI exceedingly low, generally lower than risk of CT-induced malignancies. Therefore CT scans are not indicated for most patients in this group.

Figure 41-7. Suggested computed tomography algorithm for **(A)** children younger than 2 years and **(B)** children aged 2 year and older with GCS scores of 14-15 after head trauma. (Adapted from Kuppermann N, et al: Identification of children at very low risk of clinically important brain injuries after head trauma: A prospective cohort study. Lancet 374:1160-1170, 2009.)

penetrating foreign object. Skull fractures are more clinically significant in children than in adults. Fractures, especially complex stellate or multiple injuries, are often seen in abused children, and skull films should be obtained if abuse is suspected. *Ping-Pong fractures* occur with concentrated forces that indent the skull. These fractures are unique to infants and appear as multiple indentations in the skull with no significant bone discontinuity. Skull fractures are common in children who have sustained deep scalp lacerations or who have a large scalp hematoma.

Post-traumatic leptomeningeal cysts or *growing skull fractures* are delayed complications of linear skull fractures in infancy. If a tear in the dura accompanies the linear fracture, the meninges may fill with CSF and prolapse through the fracture margins, thus preventing fracture healing.[23,139] These cysts can grow in size and have the potential to cause a mass effect. If a linear fracture is found by skull radiography, close follow-up is indicated to assess for this rare delayed complication.

Overall, children who sustain severe head injury have lower mortality and a better neurologic outcome than comparably injured adults. This is probably because of the neuroplasticity of the young brain; however, in children younger than age 2 years, the prognosis after severe head injury is poor.[152] Very young children have immature cerebrovascular autoregulation, which increases the risk of cerebral edema formation. The immature brain has increased susceptibility to permanent injury because of incomplete myelination.

The emergency evaluation of children with minor head injury is especially challenging, given their potentially dramatic presentation and the added difficulty of obtaining an accurate neurologic assessment. Evidence-based consensus guidelines have been proposed for the evaluation and management of minor head injury in children.[23,127,138,139] Parents should be educated about the warning signs and symptoms of delayed complications of minor head trauma.

PENETRATING HEAD INJURIES

Epidemiology

Penetrating brain injury (PBI) occurs at a rate of 12 per 100,000 population and can be caused by missile injuries or impalement.[153] The United States has the highest penetrating head injury rate among developed countries in the world, with the most common cause being gunshot wounds (GSWs). These dramatic injuries are increasing in frequency, and the neuroscientific understanding of the complicated cerebral events that occur with penetrating head injury does not yet equal our understanding of the pathophysiology of blunt injuries.

Civilian GSWs to the head account for approximately 31,000 deaths per year, and up to 70% of all patients who sustain a GSW to the head are dead at the scene.[154,155] Overall, the mortality caused by a GSW to the head is estimated to be 90%.[156] If the patient is hemodynamically stable, has not sustained secondary systemic insults such as hypoxia or hypotension, has no expanding mass lesions from the missile injury, and has not ingested intoxicants that may interfere with assessment, prognosis after a GSW to the head can be predicted by the GCS score and pupillary responsiveness at presentation.[157] If the GCS score at presentation is less than 5, mortality approaches 100%. If the GCS score at presentation is greater than 8 and the pupils are reactive, survival approaches 75%. Survivors of GSWs to the head tend to do well, with up to 60% returning to their former employment.[157]

Pathophysiology

Missile injuries to the head can result in several different patterns of damage. *Tangential wounds* are caused by an impact that occurs at an oblique angle to the skull. If the missile has high velocity but low energy, it can travel around the skull under the scalp without passing through the skull. Intracranial damage, primarily cortical contusions, can occur at the initial site of impact because of pressure waves generated by the impact. In one study, 24% of patients with tangential GSWs also had intracranial hemorrhage, and 16% sustained skull fractures.[158,159] Many patients with tangential GSWs have a GCS score of 15 on presentation.

Perforating wounds are usually caused by high-velocity projectiles, which cause through-and-through injuries of the brain with an entrance and an exit wound. This type of injury is largely discussed within the context of military GSWs to the head.

Penetrating missile wounds are produced with moderate- to high-velocity projectiles discharged at close range. The majority of the civilian PBI literature deals with penetrating missile wounds.[156] The penetrating object may travel through the entire skull, bounce off the opposite inner table of the skull and ricochet within the brain, or stop somewhere within the cranial cavity. Bullets that penetrate the skull do not travel in a straight path. The wounding capacity of a firearm is related to the kinetic energy of its missile on impact and how much energy is dissipated in the tissues. Low-velocity missiles tend to be deflected by intracranial structures. The final track is therefore erratic and occasionally bears no relation to the exit or entrance site of the missile.[160,161] High-velocity missiles can project straight through the tissues and easily fracture bones. Flight stability and the angle at which the bullet strikes its target affect the path through the brain. Within tissue, destabilizing motions include deviation of the longitudinal axis of the bullet from a straight line (yaw), forward rotation of the bullet around its center of mass (tumbling), and oscillatory motion of the bullet axis around its center of mass (rotation). As the bullet passes through the brain, a tissue cavity is created. This cavity can be as much as 10 times the diameter of the missile. A percussion shock wave is also created, lasting 2 msec but causing little tissue destruction.[156,160,161]

The morbidity and mortality from missile injuries to the head depend on the intracranial path, speed of entry, and the size and type of the penetrating object. Projectiles that cross the midline or the geographic center of the brain, pass through the ventricles, or come to rest in the posterior fossa are associated with extremely high mortality.[157,160,161] High-velocity wounds are associated with greater mortality than low-velocity injuries. Large missiles or missiles that fragment within the cranial vault are usually fatal. The design of the bullet and its fragmentation potential (capacity to deform or fragment) also contribute to final tissue destruction and patients' morbidity and mortality.

Many GSWs to the head are intentionally self-inflicted injuries. The percentage of penetrating head injuries caused by self-inflicted GSWs ranges from 13 to 88%.[157] Characteristics of self-inflicted GSWs include injury on the dominant side, powder burns at the entrance site, and large stellate scalp lacerations caused by dissection of the subgaleal layer by exploding gases released close to the scalp. In suicide attempts, GSWs to the head tend to traverse the midline in the coronal plane and often involve major vascular structures. If the self-inflicted GSW has an entrance through the mouth, injury to the hard palate may occur with potential upper airway compromise. The careful aim and close range of self-inflicted GSWs to the head make these injuries particularly devastating; mortality is higher than with non–self-inflicted penetrating injuries, and odds ratios of death vary from 1.63 to 5.83.[157]

Clinical Features

Physical assessment of the patient with a missile wound to the head focuses on the presenting GCS score and pupillary responsiveness. The entire scalp is carefully inspected for occult GSWs. In addition to the physical damage to brain tissue caused by the penetrating injury, other devastating physiologic changes occur immediately after injury. ICP increases, the BBB breaks down, CBF is altered, and cerebral edema develops. Cerebral autoregulation is lost, and CPP may fall.

Management

The ED management is directed at reducing the occurrence of the secondary systemic insults of hypoxia and ischemia, with emergent intervention if signs of herniation syndrome develop and the patient is viable. Management should be aggressive until the prognosis can be established by examination and neuroimaging data. When penetration of the cranial vault is established, the patient should be intubated. If the physician waits for coma before intubating the patient, mortality approaches 100%.

Emergency treatment should include intravenous antibiotics because penetrating missiles are contaminated with skin, bone, and hair. Tissue contamination may be widespread because of the cavitation caused by the missile as it passes through the brain.[162] Approximately 90% of all CNS infections associated with penetrating TBI injuries occur within 6 weeks. Most neurosurgeons do not automatically débride bone and missile fragments owing to a growing body of literature that shows no evidence that removal of these foreign bodies decreases infection rate.[18,156]

Between 30 and 50% of patients with PBI develop seizures; 10% of these occur in the first week.[18,156] Anticonvulsants should be given in the acute setting to prevent early PTSs in the patient with PBI, especially if the patient is to be transported to another institution after acute stabilization. Anticonvulsants should not be given beyond the first week after PBI because this has not been shown to prevent the development of late seizures.

Skull radiographs may be useful in determining the number of penetrating fragments and their track. A CT scan defines the precise location of the missile, its intracranial path, the presence

www.ketabpezeshki.com 66485457-66963820

of bone or missile fragments, extra-axial or intracerebral blood collections or other traumatic lesions, and pneumocephalus. CT scanning is the radiologic test of choice for PBI.[163] Pneumocephalus is often associated with missile wounds that penetrate the sinuses but can be caused by free air sucked into the penetration cavity behind the projectile.

All tangential GSWs should be evaluated with a head CT scan secondary to the high incidence of associated intracranial injury.[159] When a penetrating head injury is caused by *impalement,* the penetrating object should be left in place to be removed at surgery. A skull radiograph shows the size of the object, the angle of impalement, and the depth of penetration. Angiography may be indicated to better discern location referable to key vascular structures.

COMPLICATIONS AFTER HEAD INJURY

Neurologic Complications

Seizures

PTSs are relatively common in the acute or subacute period. Acute PTSs are usually brief and are probably caused by transient mechanical and neurochemical changes within the brain. After the acute seizure, the patient often has no additional seizure activity. In the subacute period, 24 to 48 hours after trauma, seizures are caused by worsening cerebral edema, small hemorrhages, or penetrating injuries. PTSs are common in children and can be precipitated by relatively minor head injury.[164] Acute PTS prophylaxis in the ED is recommended for some head-injured patients even if they have not had a seizure (see Box 41-2).[78,80,164] This is especially important in patients who will have neuromuscular blockade to facilitate management or transfer because the clinical manifestations of seizures are lost in these patients. Phenytoin and fosphenytoin are used as first-line agents for prophylaxis. The decision to maintain the head-injured patient on long-term anticonvulsant therapy during the recovery period depends on the patient's subsequent course. Long-term seizure prophylaxis is not indicated for all patients who have had PTSs in the acute or subacute period. The utility of prophylactic anticonvulsants to prevent late PTSs has not been proved, and their use is not recommended.[78] However, if a seizure occurs after the acute or subacute period, anticonvulsants are indicated. TBI has been estimated to account for 20% of all epilepsy in the general population.[165,166] It is the leading cause of epilepsy in young adults. In a longitudinal cohort study following individuals with moderate and severe head injury, Yasseen and colleagues[167] found that 9% of this population was being treated for epilepsy. Estimates of late PTSs in patients with moderate and severe TBI range from 4.2 to 25.3% and manifest themselves as long as 12 years postinjury.[168]

Central Nervous System Infections

Meningitis after Basilar Fractures. Post-traumatic meningitis is caused by a variety of microbes, depending on the portal of bacterial entry. Patients have typical signs and symptoms of meningitis, including fever, altered mental status, and occasional focal neurologic signs. In patients with a CSF leak after basilar fracture, early meningitis (i.e., within 3 days of injury) is usually caused by pneumococci. Ceftriaxone or cefotaxime is a reasonable antibiotic choice with the addition of vancomycin. Gram-negative organisms often cause meningitis that develops more than 3 days after trauma.[169] A third-generation cephalosporin, with nafcillin or vancomycin added to ensure coverage of *Staphylococcus aureus,* should be started. In children, post-traumatic meningitis may be caused by *Haemophilus influenzae.* Prophylactic antibiotics are not consistently recommended in the acute setting in patients with CSF leaks caused by basilar skull fractures during the first 7 days.[169] However, Friedman and colleagues found that prophylactic antibiotics administered in the first week reduced meningitis risk by one half.[170] The risk of meningitis does increase after 7 days of CSF leakage, and prophylactic antibiotics may be warranted.[171]

Brain Abscess. Brain abscesses develop infrequently after penetrating missile injuries to the head. Abscesses can also develop after open depressed skull fractures if bone fragments are not removed or as a postoperative complication. Post-traumatic CSF fistulae and fractures that disrupt air-filled sinuses predispose to the formation of brain abscesses. Clinical manifestations include headaches, nausea, vomiting, declining mental status, signs of increased ICP, or new focal neurologic findings in patients who had been improving after trauma. Occasionally, nuchal rigidity, hemiparesis, or seizures may be present. Systemic signs are often subtle, and CSF leukocytosis may be absent.

Contrast-enhanced CT scanning makes the diagnosis of brain abscess. A ring pattern with a low-density center is characteristic. The enhanced ring represents surrounding altered vascular permeability and therefore is also seen in the cerebritis stage early in abscess formation. Lumbar puncture is often not helpful and should not be performed in the patient with signs of increased ICP (e.g., headache, vomiting, and papilledema).

The treatment of brain abscess is usually operative drainage. The patient with cerebritis may respond to intravenous antibiotics but requires close monitoring with repeated CT scans. Common organisms isolated from post-traumatic abscesses are *S. aureus* and gram-negative aerobes.[169]

Cranial Osteomyelitis. Cranial osteomyelitis can occur after penetrating injury to the skull. The clinical manifestations include pain, tenderness, swelling, and warmth at the infected site. More than 50% of cases are obvious on plain skull radiographs.[169] Technetium bone scans can help in the diagnosis when the skull radiographs are negative, but false-positive bone scans occur in patients with previous trauma or craniotomy. Adding a gallium scan helps to differentiate infection from other causes of a positive technetium scan. Patients with post-traumatic cranial osteomyelitis require surgical débridement and removal of the infected bone. Antibiotic choice is determined by culture results. If systemic symptoms are present, an underlying subdural or epidural empyema is often present.

Medical Complications

Disseminated Intravascular Coagulation

The injured brain is a source of tissue thromboplastin that activates the extrinsic clotting system. Disseminated intravascular coagulation (DIC) can develop within hours after any injury disrupting brain tissue. It has been detected in nearly all patients with severe TBI.[93,172] DIC increases morbidity and mortality after severe head trauma as well as the risk of delayed intracranial hemorrhage. If a stable patient with DIC suddenly deteriorates, a repeat CT scan should be obtained to rule out hemorrhage.

The extent of tissue destruction determines the degree of DIC that develops. The diagnosis is based on abnormalities in INR, prothrombin and partial thromboplastin time, platelets, plasma fibrinogen levels, and fibrin degradation products. Patients with coagulopathy or abnormal platelet function require interventions to correct these. Patients with moderate or severe head trauma are at extremely high risk to experience venous thromboembolic events (VTEs) after admission to the hospital. Recent evidence suggests that patients with moderate or severe head trauma can be safely treated with low-molecular-weight heparin to reduce the risk of VTE without significantly increasing the risk of intracerebral hematoma expansion.[172]

www.ketabpezeshki.com 66485457-66963820

Neurogenic Pulmonary Edema

Neurogenic pulmonary edema can develop minutes to days after head trauma. Two theories exist on its pathophysiology: catecholamine surge or blast with elevated hydrostatic forces and increased capillary permeability directly caused by brain injury versus a systematic inflammatory reaction.[173-175] Lowering the ICP appears to reverse the neurogenic stimulation that causes this edema.[176] Close ventilator management is essential to improved outcomes in patients with acute lung injury secondary to TBI.[175]

Cardiac Dysfunction

A variety of cardiac rhythm, rate, and conduction abnormalities are detected after head injury. Harvey Cushing noted a connection between cardiac dysrhythmias and intracranial bleeding in the beginning of the 20th century.[177] These abnormalities can be life-threatening and require aggressive therapy. In addition, adequate cardiac output is essential in head-injured patients to ensure cerebral perfusion. Many head-injured patients with cardiac dysfunction have concurrent myocardial injury from underlying disease or from chest injury. However, brain injury can cause primary cardiac dysfunction. Cardiac rhythm abnormalities have been reported in up to 70% of all patients with SAH and more than 50% of all patients with intracranial hemorrhage.[34,174] In SAH the cardiac dysrhythmias may result from autonomic nervous system dysfunction that subsequently affects ventricular polarization. High levels of circulating catecholamines have been measured in head-injured patients, with increased sympathetic nervous system activation.[34]

The most common cardiac dysrhythmia after head injury is *supraventricular tachycardia,* but many other rhythms have been observed. Findings on the electrocardiogram include diffuse large upright or inverted T waves, prolonged QT intervals, ST segment depression or elevation, and U waves. The primary goal in the emergency management of cardiac dysfunction after head trauma is ensuring adequate tissue perfusion and avoiding hypoxia. Dysrhythmias in head-injured patients often resolve as ICP is reduced.[34,174] Standard advanced cardiac life support protocols should then be used because concurrent cardiac injury may also be present in multiply traumatized patients.

SPECIFIC INJURIES

Scalp Wounds

Scalp lacerations are extremely common after head injury and may be a source of significant bleeding because hemostasis may be difficult to achieve. Methods to achieve hemostasis include direct digital compression of the bleeding vessel against the skull, infiltration of the wound edges with lidocaine with epinephrine, and ligation of identified bleeding vessels. If the galea is lacerated, it can be pulled up with a clamp and its edges folded over the lacerated skin edges to tamponade the bleeding vessels. Raney scalp clips applied to the edges of the wound are also effective. In stable patients, quick closure of the wound, after proper débridement and irrigation, is the most effective way to stop a bleeding scalp laceration and prevent the tissue crush injury that may occur if other compressive methods are used for too long.

When hemostasis is obtained, the wound should be irrigated to rinse away any debris. The emissary vessels of the subgaleal layer of the scalp drain directly into the diploë veins of the skull. These in turn drain into the venous sinuses. Contaminated or infected scalp wounds therefore have the potential to cause serious intracranial infections. Blood clots and other debris should be removed and the galea and underlying cranium palpated to detect any remaining debris, disruptions, or bone step-offs. Shear injuries to the scalp may deposit contaminants at sites distant from the apparent injury. The complexity of stellate lacerations often interferes with thorough inspection and débridement; stellate lacerations are particularly susceptible to infection. Digital exploration of a scalp wound should be carefully performed; if it is done too vigorously, comminuted or depressed bone pieces may be depressed further.

It is easy to confuse a disruption in the galea or a tear in the periosteum with a skull fracture. The base of the laceration should therefore be directly visualized. Clipping away a small area of hair parallel to the edges of the wound may facilitate this. Alternatively, an antibiotic ointment can be applied to the hair immediately surrounding the wound and used to plaster the hair away from the injury site. If the laceration begins on the forehead and extends upward beyond the hairline, surrounding hair should not be removed. Removal obliterates a useful landmark for cosmetic closure and may result in malalignment of the two laceration edges. If hair is accidentally embedded within the repaired laceration, it can delay healing by producing an inflammatory reaction or by serving as a nidus of infection.

Disruption of the galea results in a gaping scalp laceration. Large lacerations of the galea are closed to prevent the edges of the wound from pulling apart as the muscles within the galea contract. The skin, dermis, and galea can usually be repaired in a single layer with interrupted or vertical mattress sutures of 0-3.0 nylon or polypropylene.[178] Several recent studies have evaluated the use of staples versus sutures to close scalp lacerations that do not involve the galea. For both adult and pediatric scalp lacerations that begin beyond the hairline, staples have been shown to be cheaper, take less time, and have the same outcome than sutures if used in the appropriate manner.[179-181] Staples cannot be used to close the galea and may not be effective alone when hemostasis is a problem.[181] Recently an alternative method of scalp laceration closure has been described in which bundles of the patient's hair on each side of the wound are twisted together and then secured with tissue glue.[182,183] This may provide another method of effective repair and prevent the need to remove the closure material after the wound has healed.

Because of the rich blood supply of the scalp, even very large scalp avulsions can survive. If the avulsion remains attached to the rest of the scalp by a tissue bridge, it should be reattached to the surrounding tissue. If the avulsion is completely detached from the scalp, it should be treated as any other amputated part and reimplanted as soon as possible.[178] Scalp abrasions are often contaminated with pieces of dirt or other debris. The wound should be cleaned as thoroughly as possible and inspected for puncture wounds or other areas that penetrate beyond the superficial layers of the skin to ensure the removal of unsuspected foreign bodies. A careful inspection often reveals a small scalp laceration within the abraded area. Antibiotics are usually not needed for carefully managed scalp wounds because rapid healing is facilitated by the rich blood supply of the scalp.

Skull Fractures

Clinical Assessment and Significance

Skull fractures are local injuries caused by direct impact to the skull. The presence of a skull fracture does not always indicate underlying brain injury. However, the force required to fracture the skull is substantial, and all patients with skull fractures are carefully evaluated to ensure that no additional injury is present. With increasing severity of head injury, the likelihood of skull fracture increases, and the presence of a skull fracture after trauma increases the likelihood of a TBI.[184-186] It is often difficult to predict the presence of a skull fracture by clinical examination, and if this can be done, it is likely that substantial underlying brain injury is

www.ketabpezeshki.com 66485457-66963820

also present. The pattern, extent, and type of skull fracture depend on the force of the impact applied and the ratio of the impact force to the impact area. The fracture usually starts at the point of maximum impact.

Clinically significant skull fractures result in intracranial air and pass through an air-filled space (e.g., sinus), are associated with an overlying scalp laceration (open skull fracture), are depressed below the level of the skull's inner table, or overlie a major dural venous sinus or the middle meningeal artery.[166,187]

A noncontrast head CT scan with bone windows has become the imaging modality of choice for patients with suspected skull fractures.[186,187] Plain radiographs can be useful when CT scan is not available; if an intracranial foreign body or a linear or depressed fracture is detected, a noncontrast head CT is indicated to rule out intracranial traumatic pathology.[187]

Linear Fractures

A linear skull fracture is a single fracture that goes through the entire thickness of the skull. Linear skull fractures are clinically important if they cross the middle meningeal groove or major venous dural sinuses; they can disrupt these vascular structures and cause the formation of EDHs. Most other linear skull fractures are not clinically significant

Sutural diastasis is the traumatic disruption of a cranial suture. In adults, sutural diastasis often involves the coronal or lambdoid sutures. Sutural diastasis usually occurs when a linear fracture extends into the suture line, and it is rare after sutures have undergone bone fusion *Comminuted* skull fractures are multiple linear fractures that radiate from the impact site. Usually this injury suggests a more severe blow to the head than that producing a single linear fracture. A linear *vault* fracture substantially increases the risk of intracranial injury.

Patients with nonsignificant linear fractures can usually be discharged from the ED with competent home observation. In patients with significant linear fractures, admission for observation is warranted.[186]

Depressed Fractures

Depressed skull fractures are clinically important because they predispose to significant underlying brain injury and to complications of head trauma, such as infection and seizures. When a depressed fracture occurs, traumatic impact drives the bone piece below the plane of the skull. The edges of the depressed portion of skull may become locked underneath the adjacent intact bone and fail to rebound into their previous position. As a result, the depressed piece of bone can penetrate tissue and lacerate the dura. Depressed skull fractures are usually caused by direct impact injury with small blunt objects, such as a hammer or a baseball bat. Most depressed skull fractures occur over the parietal or temporal regions. If the free piece of bone is depressed deeper than the adjacent inner table of the skull, most neurosurgeons consider this injury significant enough to require surgical elevation.[23,186]

When a CT scan is not available, detection of depressed skull fractures can be attempted with plain radiographs. However, depressed fractures may be difficult to visualize on plain skull radiographs. The free piece of bone demonstrates increased or double density because it often overlaps the nonfractured bone, or it is viewed relatively rotated from the rest of the adjacent cranium. Tangential views of the skull may increase the ability to visualize the fracture.

Depressed skull fractures are most often open fractures with disruption of the galea. They can often be felt with palpation of the skull beneath a scalp laceration. This examination should be done cautiously to avoid driving a depressed bone fragment deeper into the cranial tissue. The clinical examination for a depressed skull fracture may be misleading. The mobility of the scalp can result in nonalignment of the fracture with an overlying scalp laceration. As a result, the skull underlying the laceration may be normal, with the depressed area several centimeters away. Scalp swelling may also interfere with physical examination findings and hide any palpable bone defects. The signs and symptoms of a depressed skull fracture depend on the depth of depression of the free bone piece. About 25% of patients sustaining a depressed skull fracture report LOC.[186] Neurologic deficits may be present, depending on the extent of underlying brain tissue injury.

A CT scan is indicated for patients with a history or physical examination findings that suggest a depressed skull fracture. The CT scan should include bone windows to determine the depth of depression and the presence of concurrent traumatic intracranial lesions. Patients with depressed skull fractures should be admitted for continued observation.

Depressed skull fractures, as well as any type of penetrating skull injury, may increase the risk for developing seizures.[188] ED patients suspected of having a depressed skull fracture warrant prophylaxis for PTSs, especially if they have an altered level of consciousness or require chemical paralysis. Depressed skull fractures may also increase the risk for intracranial and meningeal infections; patients with depressed skull fractures should receive prophylactic antibiotics.[23,166,186,188]

Basilar Fractures

Basilar fractures are linear fractures at the base of the skull. The fracture usually occurs through the temporal bone, with bleeding into the middle ear producing hemotympanum. Patients with basilar fractures are at risk for extra-axial hematomas because of the proximity of the fracture to the middle cerebral artery. Often, the fracture has caused a dural tear, which produces a communication among the subarachnoid space, the paranasal sinuses, and the middle ear. This offers a route for the introduction of infection into the cranial cavity and is suggested by a CSF leak.[23] As with linear skull fractures, a basilar fracture is not always associated with significant underlying brain injury; these fractures are the result of considerable impact force, however, and TBI must be ruled out.

Basilar fractures can compress and entrap the CNs that pass through the basal foramina, can dislocate the bones of the auricular chain, and can disrupt the otic canal or cavernous sinuses, with subsequent injury to CNs III, IV, and V. Fractures of the sphenoid bone can disrupt the intracavernous internal carotid artery, creating the potential for the formation of pseudoaneurysms or carotid venous fistulae. The diagnosis of a basilar skull fracture is based on associated clinical signs and symptoms (see Box 41-1).

Patients with clinical evidence suggesting a basilar skull fracture should have a CT scan, to define the fracture and to rule out concurrent intracranial pathology, and should be admitted for observation. Because the basilar skull fracture may afford an entrance for bacteria, antibiotics are often considered. However, most CSF leaks resolve spontaneously in about 1 week with no complications, and, in general, antibiotics are not given prophylactically during the first week of CSF rhinorrhea.[23] Counter to this approach, Friedman and colleagues found prophylactic antibiotics to reduce the risk of meningitis by half.[170] If a patient with a previously diagnosed CSF leak returns to the ED later with fever, the diagnosis of meningitis should be strongly suspected and appropriate workup (i.e., lumbar puncture) and antibiotic treatment initiated immediately.

Open Fractures

A skull fracture is open when a scalp laceration overlies a fracture. If the fracture has disrupted the dura, a communication exists between the external environment and the brain. A fracture that

www.ketabpezeshki.com 66485457-66963820

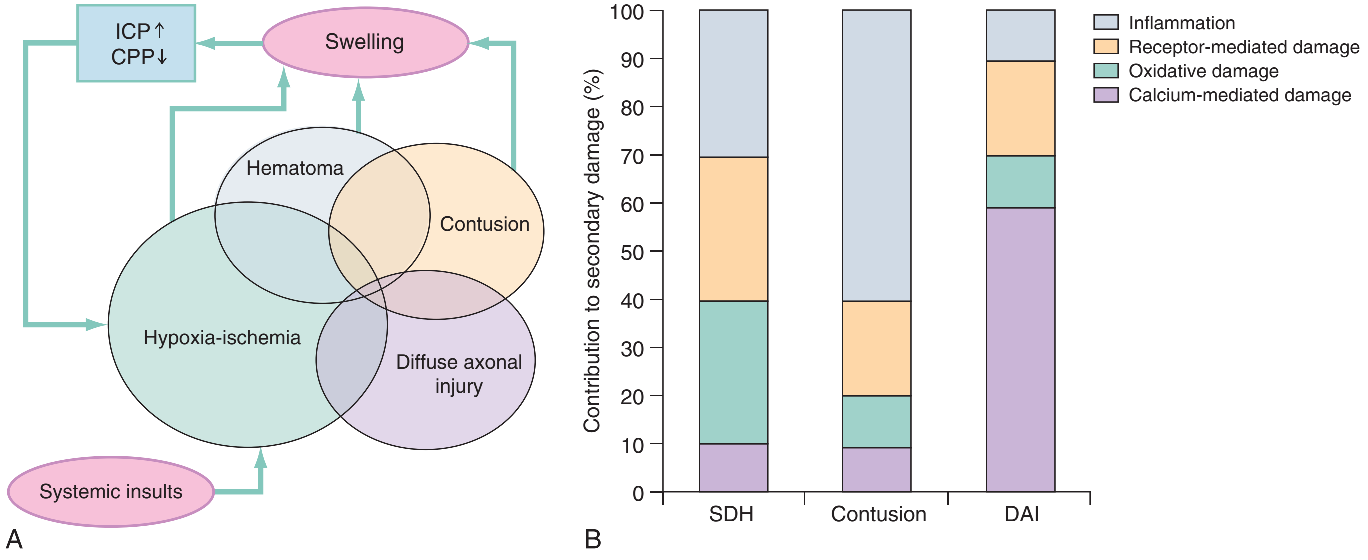

Figure 41-8. Multiple contributing factors in the pathophysiology of head trauma section. *CPP,* cerebral perfusion pressure; *DAI,* diffuse axonal injury; *ICP,* intracranial pressure; *SDH,* subdural hematoma. disrupts the paranasal sinuses or the middle ear structures is also considered open. An open skull fracture requires careful irrigation and débridement. Blind probing of the wound should be avoided because it can introduce contaminants into the wound and can further depress comminuted fracture pieces.

Diffuse Axonal Injury

Prolonged traumatic coma not caused by mass lesions, ischemic insult, or nontraumatic causes of coma is thought to result from DAI. DAI or diffuse traumatic axonal injury is a pathologic process in which axons sustain a primary insult in which they are torn (axotomy) and secondary insults that can result in progressive cellular pathologic changes and eventual axon death (Fig. 41-8).[155] Affected axons are dispersed between areas of undamaged cells (Fig. 41-9). Badly damaged axons become edematous and eventually begin to separate from one another, causing widespread disruption of cortical physiology and microanatomy in the white matter of the brain and brainstem. Complete separation of axons does not always cause cell death; acute uncoupling of CBF and metabolism and apoptosis are thought to be the primary factors linked to axonal cell death after DAI.[21,155] Experimental laboratory data have indicated that neurons can partially repair and regenerate damaged axons. Recovery depends on the reversal or correction of structural and physiologic abnormalities.[17]

DAI is thought to be the cause of persistent traumatic coma that begins immediately at the time of trauma; however, some patients with DAI may recover consciousness briefly before lapsing into prolonged coma. No specific acute focal traumatic lesions are noted on a head CT scan. MRI is more sensitive in detecting subtle injury in DAI, but it is often not practical to perform MRI on critically injured patients. Occasionally, small petechial hemorrhages in proximity to the third ventricle and within the white matter of the corpus callosum or within the internal capsule of the brainstem are detected. DAI is the most common CT finding after severe head trauma, estimated to occur in 50% of all comatose head-injured patients.[166]

Because diagnostic studies cannot predict the extent of the axonal damage, the severity of the injury is determined by the clinical course. Patients with *mild* DAI are in coma for 6 to 24 hours. Approximately one third of patients with mild DAI demonstrate decorticate or decerebrate posturing, but by 24 hours they are following commands.[166] The mortality in this group is 15% and is associated with infectious complications or concurrent intracranial injuries. Most patients who recover have mild or no permanent disabilities.

Moderate DAI is the most common clinical picture. Patients with moderate DAI are in coma for longer than 24 hours. Often, they are victims of falls or vehicular crashes and have associated basilar skull fractures. Patients may exhibit transient decortication or decerebration but eventually recover purposeful movements. On awakening, patients have prolonged severe post-traumatic amnesia and moderate to severe persistent cognitive deficits. Almost 25% die of complications of prolonged coma.[166]

Severe DAI is almost always caused by vehicular crashes. Patients remain in coma for prolonged periods and demonstrate persistent brainstem dysfunction (posturing) and autonomic dysfunction (e.g., hypertension and hyperpyrexia). Diffuse brain swelling subsequent to injury causes intracranial hypertension. Herniation syndrome can occur if elevated ICP does not respond to medical or surgical intervention. Some patients with severe DAI eventually awaken but are severely disabled. Some patients remain in a persistent vegetative state, but most with severe DAI die from their head injury. All patients with DAI have an identical presentation of coma. Recent research has identified several biomarkers that may have clinical relevance in the future.[155] However, currently no early clinical or biomarker predictor exists that differentiates patients with mild, moderate, or severe DAI.

Cerebral Contusions

Contusions are bruises on the surface of the brain, usually caused by impact injury. Most often, contusions occur at the poles and the inferior surfaces of the frontal and temporal lobes where the brain comes into contact with bone protuberances in the base of the skull. If the contusion occurs on the same side as the impact injury, it is a *coup injury;* if it occurs on the opposite side, the contusion is a *contrecoup injury.* Contusions also often develop in the brain tissue that underlies a depressed skull fracture. Multiple areas of contused tissue may be produced with a single impact, often in association with other intracranial injuries.

Contusions are produced when parenchymal blood vessels are damaged, resulting in scattered areas of petechial hemorrhage and subsequent edema. Contusions develop in the gray matter on the

www.ketabpezeshki.com 66485457-66963820

surface of the brain and taper into the white matter. Often, subarachnoid blood is found overlying the involved gyrus. With time, the associated hemorrhages and edema of a contusion can become widespread and serve as a nidus for hemorrhage or swelling, thus producing a local mass effect. Compression of the underlying tissue can cause local areas of ischemia, and tissue infarction is possible if the compression is significant and unrelieved. Eventually, these ischemic areas become necrotic, and cystic cavities form within them.

The clinical presentation of patients with contusions is frequently delayed. They may have sustained only a brief LOC, but the duration of post-traumatic confusion and obtundation may be prolonged. If contusions occur near the sensorimotor cortex, focal neurologic deficits may be present. Many patients with significant contusions make uneventful recoveries, but contusions may cause significant neurologic problems, including increased ICP, PTSs, and focal deficits. Agrawal and colleagues[189] showed that significant progression of cerebral contusions is not an infrequent occurrence. Patients with lower GCS scores and larger cerebral contusions are at higher risk for needing delayed surgical intervention.[189]

Non–contrast-enhanced CT is the best diagnostic test to discover contusions in the early post-traumatic period. These appear heterogeneous and irregular because of mixed regions of hemorrhage, necrosis, and infarction. Often, the surrounding edematous tissue appears hypodense. By post-trauma days 3 and 4, the blood located within the contusions has begun to degrade, and MRI becomes more useful.

Epidural Hematoma

EDHs are blood clots that form between the inner table of the skull and the dura. Most EDHs are caused by direct impact injury that causes a forceful deformity of the skull. Often, a fracture occurs across the middle meningeal artery, vein, or a dural sinus.

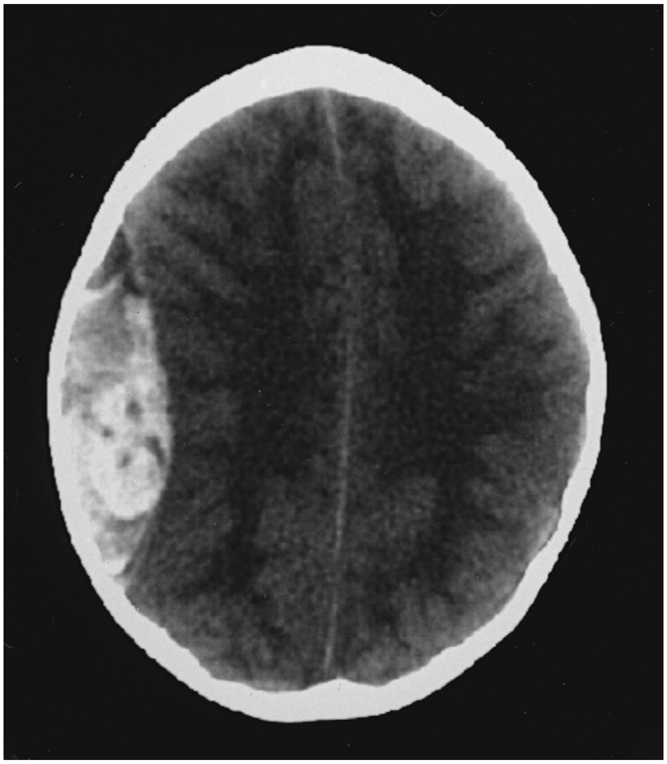

Figure 41-9. Non–contrast-enhanced computed tomography scan of acute epidural hematoma at the level of right midconvexity. There is an associated mass effect and moderate midline shift.

The temporoparietal region is the most likely site for an EDH.[159] The high arterial pressure of the bleeding vessel dissects the dura away from the skull, permitting the formation of the hematoma.

An EDH is usually unilateral, and 20% of patients have other intracranial lesions, usually SDHs or contusions.[23] The deterioration of a patient who has an EDH from arterial bleeding can be rapid and dramatic. Because of their rapid formation, EDHs from arterial bleeding are usually detected within hours after injury and often earlier in children. EDHs that develop from a dural sinus tear develop more slowly, and clinical manifestations may be delayed, with resultant delays in detection.

EDH is primarily a disease of the young and accounts for 2.7 to 4% of all patients who have experienced TBI.[23,190] EDHs are rare in elders and children younger than 2 years of age because of the close attachment of the dura to the skull in both patient populations. The classic presentation of an EDH is described as head trauma producing a decreased level of consciousness followed by a "lucid" interval. Although the patient's consciousness is less decreased during the lucid interval, a completely normal mental status may not return before a second episode of decreased consciousness occurs. The lucid interval is not pathognomonic for an EDH and occurs in patients who sustain other expanding mass lesions. Approximately 47% of patients with EDHs present classically.[190] The development of symptoms and signs of EDH is entirely dependent on how quickly the EDH is developing within the cranial vault. Patients with an EDH often complain of a severe headache, sleepiness, dizziness, nausea, and vomiting. A small EDH may remain asymptomatic, but this is rare.

If the patient is not in coma when the diagnosis of EDH is established and if the condition is rapidly treated, the mortality is 5 to 10%. If the patient is in coma, the mortality from EDH is approximately 20%. The mortality in pediatric patients undergoing surgical evacuation is 5%.[190] If the EDH is rapidly detected and evacuated, the functional outcome is excellent.

On CT scan, an EDH appears hyperdense, biconvex, ovoid, and lenticular. The EDH does not usually extend beyond the dural attachments at the suture lines. The margins are sharply defined, and the hematoma usually bulges inward toward the brain (see Fig. 41-9). EDHs of mixed density on CT may be actively bleeding.

A posterior fossa EDH is the most common traumatic mass lesion of the posterior fossa and accounts for 5% of EDHs.[23] Direct occipital trauma resulting in a skull fracture that disrupts a venous sinus is the usual cause, and most patients have external evidence of occipital injury. Most patients become symptomatic within 24 hours after injury, with complaints of headache, nausea, vomiting, and nuchal rigidity. Most patients eventually have a decreased level of consciousness. On CT scan, a posterior fossa EDH looks similar to other EDHs, but it may cross the midline and extend above the tentorium to the supratentorial compartment (Fig. 41-10). Expert consensus guidelines support rapid surgical evacuation for any patient who has mass effect on CT or progressive neurologic deterioration.[175] Mortality approaches 26%.[23]

Recent studies have investigated the indications for immediate operative intervention for EDHs. Epidurals greater than 30 cm^3 in volume should be evacuated surgically, regardless of the patient's GCS score. Furthermore, it is strongly recommended that comatose patients with an acute EDH and anisocoria on pupillary examination undergo surgical evacuation as soon as possible.[190]

Subdural Hematoma

SDHs are blood clots that form between the dura and the brain. Usually they are caused by the movement of the brain relative to the skull, as seen in acceleration-deceleration injuries. These hematomas are common in patients with brain atrophy, such as alcoholic or elder patients. In these patients, the superficial bridging vessels traverse greater distances than in patients with no

www.ketabpezeshki.com 66485457-66963820

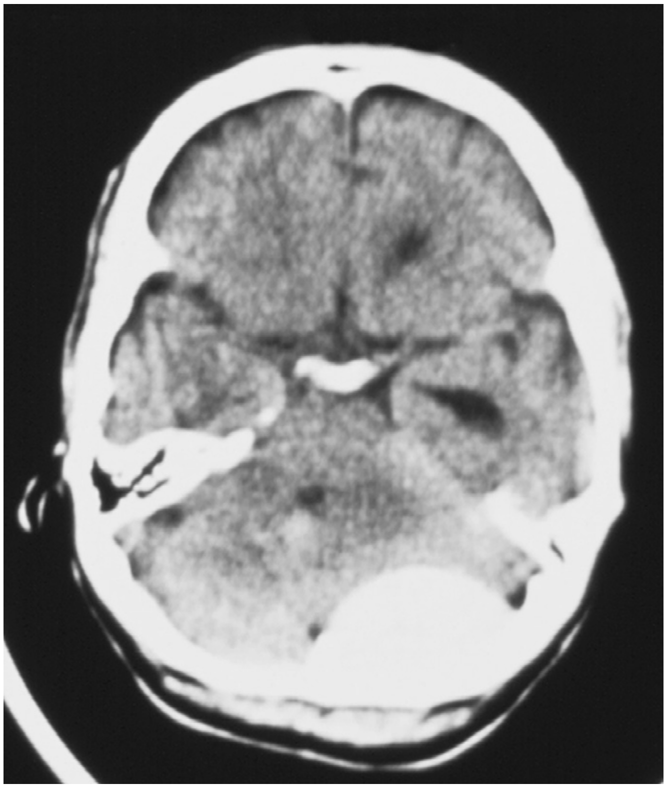

Figure 41-10. Non–contrast-enhanced computed tomography scan of large left posterior fossa, epidural hematoma. The size of the lesion at this high level suggests that it crosses into the supratentorial compartment. This lesion is often associated with occipital bone fracture that disrupts transverse sinus.

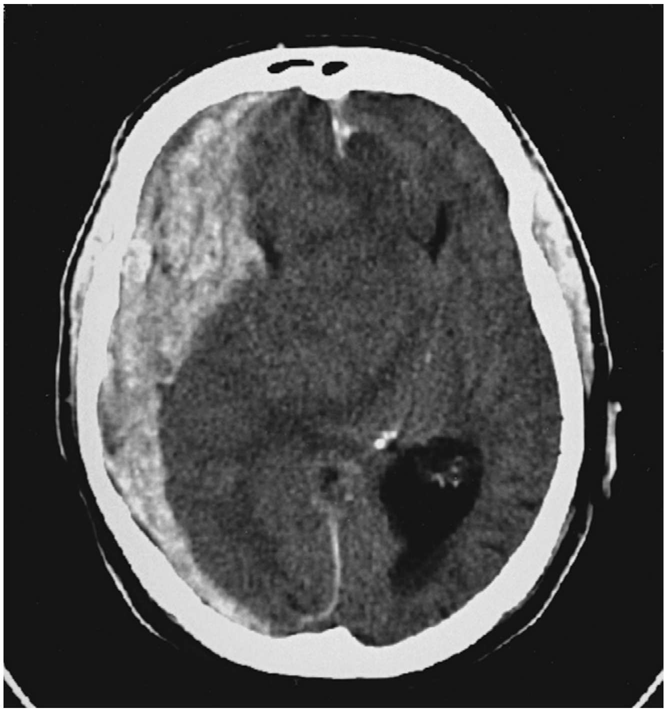

Figure 41-11. Non–contrast-enhanced computed tomography scan of acute right temporal subdural hematoma. There is acute bleeding as well as delayed bleeding, which explains the mixed density. Mass effect is large, with midline shift measuring approximately 2.7 cm right to left. The right lateral ventricle has been obliterated.

atrophy. As a result, the vessels are more likely to rupture with rapid movement of the head. Once they are ruptured, blood can fill the potential space between the dura and arachnoid.

SDHs are more common than EDHs, occurring in up to 30% of patients with severe head trauma.[159] The slow bleeding of venous structures delays the development of clinical signs and symptoms. As a result, the hematoma compresses the underlying brain tissue for prolonged periods and can cause significant tissue ischemia and damage.

The patient's clinical presentation depends on the amount of brain injury sustained at the time of trauma and the rate of SDH expansion. If the patient with an SDH was rendered unconscious at the time of trauma, the prognosis is poor; these patients often have concurrent DAI. The signs and symptoms after injury that produces an SDH are initially related to the other intracranial injuries that may have been sustained and then to the slow expansion of the SDH.

SDHs are classified by the time to clinical presentation. *Acute* SDHs are symptomatic within 24 hours after trauma. Patients with acute SDHs often have a decreased level of consciousness. Most patients with an SDH have a GCS score less than 8. Approximately 12 to 38% of patients will have a lucid period at some point in their presentation. The overall mortality of patients who have an SDH and require surgical intervention is 40 to 60%.[159]

Because of associated brain injury caused by the SDH, the delay in clinical signs and symptoms, and the more advanced mean age of the at-risk population, the mortality associated with SDH is much higher than that associated with EDH. Pupil inequality, motor deficit, and other signs consistent with increased brain swelling may be present on the initial examination. If the patient is deeply comatose at presentation with flaccidity and without signs of brainstem activity, supportive care should be considered in the ED. Subsequent management decisions should be discussed with the patient's family and the attending neurosurgeon.

If the SDH is very small (only a few millimeters thick at its widest point on CT scan), some neurosurgeons may choose careful observation for these patients. Even a small SDH may be accompanied by extensive brain tissue damage that can cause an increase in ICP sufficient to precipitate a herniation syndrome. Current consensus guidelines recommend that acute SDHs with a thickness greater than 10 mm or a midline shift of more than 5 mm on CT should be evacuated surgically, regardless of the patient's GCS score.[159] Research indicates that the longer the time between clinical worsening and operative treatment, the worse the patient's clinical outcome. In these cases, surgical evacuation should be performed as soon as possible.[159]

Unlike EDHs, SDHs often extend beyond the suture lines (Fig. 41-11). An SDH may follow the contour of the tentorium and be detected within the interhemispheric fissure (Fig. 41-12). Many patients with an acute SDH also show CT evidence of intracerebral lesions contralateral to the SDH.

A *subacute* SDH is symptomatic between 24 hours and 2 weeks after injury. It may appear hypodense or isodense on CT scans. Contrast increases detection of isodense lesions. Patients complain of a headache, altered mental status, or focal deficits. Most patients with subacute SDH require surgical evacuation of the lesion.

A *chronic* SDH becomes symptomatic 2 weeks or more after trauma. The signs and symptoms may be very subtle or nonspecific, but many patients demonstrate unilateral weakness or hemiparesis.[23] Most report an altered level of consciousness, but some patients are unable to recall their head injury or describe only a minor injury. In 20% of cases, chronic subdurals are bilateral. A chronic SDH may have initially been a small asymptomatic SDH that eventually expanded owing to a combination of recurrent

www.ketabpezeshki.com 66485457-66963820

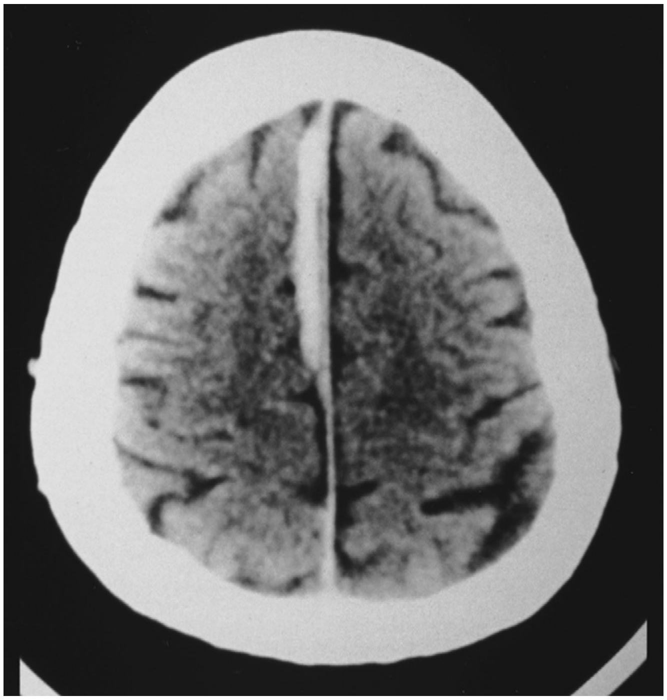

Figure 41-12. Non–contrast-enhanced computed tomography scan of intrahemispheric acute subdural hematoma.

hemorrhage and escape of plasma into the hematoma. At some point, a critical mass is reached and the chronic SDH becomes symptomatic. On CT scan, a chronic SDH may appear isodense or hypodense to brain parenchyma. In these cases, indirect evidence of the lesion includes a midline shift, effacement of the ipsilateral cortical sulci, and ventricular compression. Contrast may increase the likelihood of identifying a chronic SDH that has become isodense. On CT scan, blood of various ages is seen as a mixed-density lesion. On MRI, a chronic SDH appears hyperdense. The treatment of chronic SDHs is controversial. If they become symptomatic, chronic SDHs require surgical evacuation. Most patients have a good outcome after surgery. Overall, the mortality from surgically drained chronic SDH approaches 4%, with decreased survival in elders.[23]

The prognosis of SDH does not entirely depend on the size of the hematoma but rather on the degree of brain injury caused by the pressure of the expanding hematoma on underlying tissue or by other intracranial injury caused by the initial impact. Mortality is highest in older people, in patients who have a GCS score of 8 or less, and in those with signs of acute herniation syndrome on initial ED presentation. Posterior fossa SDHs make up less than 1% of all reported SDHs. They are caused by occipital trauma that tears bridging vessels or venous sinuses. Clinical manifestations of posterior SDH vary but usually include nausea, vomiting, headache, and decreased level of consciousness. Occasionally, CN palsies may be found, as well as nuchal rigidity, cerebellar signs and symptoms, and papilledema. On a CT scan, a posterior fossa SDH does not cross the midline or extend above the tentorium. The outcome of a posterior SDH is very poor.

In children the presence of an SDH should prompt consideration of child abuse. Many types of injury can produce SDH in children, but the infant who is repeatedly and forcibly shaken is especially susceptible.[130] Infants may have SDH because of birth trauma. In these cases the initial clinical manifestation may be a generalized seizure within the first 6 months of life. On examination the infant may have a bulging fontanel or an enlarged head circumference. A careful history may elicit long-standing constitutional symptoms, such as failure to thrive or lethargy.

Subdural Hygroma

A subdural hygroma (SDHG) is a collection of clear, xanthochromic blood-tinged fluid in the dural space. The pathogenesis of an SDHG is not certain. It may result from a tear in the arachnoid that permits CSF to escape into the dural space or effusions from injured vessels through areas of abnormal permeability in the meninges or in the underlying parenchyma. They may accumulate immediately after trauma or in a delayed manner. Clinically, an SDHG cannot be distinguished from other mass lesions. Often, patients have a decreased level of consciousness or focal motor deficits. They may complain of headaches, nausea, and vomiting. The ICP can increase because of the mass effect, and signs of increased ICP may be present on examination.

On CT scans, SDHGs appear crescent shaped in the extra-axial space. The CT density is the same as that of CSF. Bilateral SDHGs are common. If SDHGs are asymptomatic, observation is reasonable management. Otherwise, they are surgically evacuated. Mortality approaches 20% and appears to depend on the severity of other intracranial injury.[23]

Traumatic Subarachnoid Hemorrhage

Traumatic subarachnoid hemorrhage (TSAH) is blood within the CSF and meningeal intima and probably results from tears of small subarachnoid vessels. TSAH is detected on the first CT scan in up to 33% of patients with severe TBI and has an incidence of 44% in all cases of severe head trauma. It is therefore the most common CT scan abnormality seen after head injury. Data from the National Traumatic Coma Data Bank demonstrate a 60% unfavorable outcome in severely brain-injured patients in the presence of TSAH compared with a 30% unfavorable outcome if no TSAH occurs.[191] An increased incidence of skull fractures and contusions is found in patients with TSAH compared with patients with no TSAH. The amount of blood within the TSAH correlates directly with the outcome and inversely with the presenting GCS score.

Patients may complain of headache and photophobia. A noncontrast CT scan allows the diagnosis to be made, with increased density noted within the basilar cisterns. Blood can also be seen within the interhemispheric fissures and sulci.

TSAH with no other brain injury does not generally carry a poor prognosis. The most serious complication of TSAH is worsening of cerebral vasospasm, which may be severe enough to induce cerebral ischemia. Post-traumatic vasospasm is common, occurring approximately 48 hours after injury and persisting for up to 2 weeks. Calcium channel blockers (e.g., nimodipine and nicardipine) have been used in the acute intensive care unit setting to prevent or reduce vasospasm after TSAH.

Intracerebral Hematoma

Intracerebral hematomas (ICHs) are formed deep within the brain tissue and are usually caused by shearing or tensile forces that mechanically stretch and tear deep small-caliber arterioles as the brain is propelled against irregular surfaces in the cranial vault. Resulting small petechial hemorrhages subsequently coalesce to form ICHs. Approximately 85% are in the frontal and temporal lobes. They are often found in the presence of extra-axial hematomas, and in many patients multiple ICHs are present.[192,193] Isolated ICHs may be detected in as many as 12% of all patients with severe head trauma.

The clinical effects of ICH depend on size, location, and whether the bleeding is continuing. ICHs have been reported with all degrees of severity of head trauma. More than 50% of patients with ICH sustain LOC at the time of impact. The patient's subsequent level of consciousness depends on the severity of the impact

www.ketabpezeshki.com 66485457-66963820

Figure 41-13. Non–contrast-enhanced computed tomography scan of intracerebral hematoma and contusion in the left occipital region. The scan also shows layering of tentorial subdural hematoma. Mass effect and early uncal herniation are visible as well.

Figure 41-14. Non–contrast-enhanced computed tomography scan of right occipital and temporal intracerebral hematomas, surrounded by mild edema and hemorrhagic contusion. Small intrahemispheric subdural hematoma is visible in posterior interhemispheric fissure. Midline shift is obvious. Ventriculostomy has been placed and is visible as high-density image within ventricles.

and coexisting lesions. Combined with contusions, other concurrent lesions, and subsequent perilesion edema, an ICH can produce substantial mass effects and precipitate a herniation syndrome (Fig. 41-13).

An ICH may be detected on the first CT scan immediately after injury but often is not seen for several hours or days. Unlike contusions, ICHs are usually deep in the brain tissue and often become well demarcated over time. On CT scan, an ICH appears as a well-defined hyperdense homogeneous area of hemorrhage (Fig. 41-14).

Many patients with an ICH require emergent intervention or surgery to control elevated ICP. Mortality is low in patients who are conscious before surgery; in unconscious patients, mortality approaches 45%.[192,193] ICHs that bleed into the ventricles or cerebellum also carry a high mortality rate.

Traumatic Intracerebellar Hematoma

Primary traumatic intracerebellar hematomas are rare but can occur after a direct blow to the occipital area. Often, these patients also have a skull fracture or a posterior fossa EDH or SDH. Supratentorial contrecoup hematomas and contusions are also common associated findings.

The clinical presentation of an isolated traumatic cerebellar hematoma is similar to that of other posterior lesions. When other traumatic lesions are present, the picture may be quite confusing. The acute management should first address the most clinically significant lesion. The mortality from isolated traumatic intracerebellar hematoma is very high. Emergent neurosurgical consultation is indicated.

KEY CONCEPTS

Severe and Moderate Head Injuries

- These injuries require emergent noncontrast head CT.
- Patients undergo serial neurologic examinations for early detection of herniation syndrome.
- Acute herniation syndrome should initially be managed with short-term hyperventilation Surgical intervention is indicated as soon as possible.
- Long-term hyperventilation is not indicated and is detrimental.
- Mannitol or HTS should be used only in patients with increasing ICP or acute neurologic deterioration.
- Secondary systemic insults such as hypoxia and hypotension worsen neurologic outcome and should be corrected as soon as detected in the out-of-hospital or ED setting.
- Head-injured patients who have been chemically paralyzed do not have clinical manifestations of seizures; consideration should be given to prophylactic anticonvulsant administration.
- Factor VIIa has a limited role in the ED emergent management of moderate and severe head trauma. Emergency departments should have established protocols on when factor VIIa will be initiated in patients with severe and moderate head trauma.
- Most "talk and deteriorate" adult patients with moderate head injury have subdural or epidural hematomas. Early detection, CT scan, and expedient surgical intervention are the keys to a good outcome.
- Caution should given to out-of-hospital RSI in severe head injury if the intubation may be prolonged or significantly challenging. Alternative airway management should be considered.

www.ketabpezeshki.com 66485457-66963820

Minor Head Trauma

- Risk stratification of patients with minor head injury into low-risk and high-risk categories can help direct the emergency physician to an appropriate diagnostic workup.
- The decision to perform a head CT scan in patients with minor head trauma should be individualized but based on consideration of high- and moderate-risk criteria. Clinical decision-making algorithms such as the Canadian Head CT Rule are helpful to emergency medicine clinicians and their patients.
- Alcohol affects the GCS score and significantly obscures the neurologic examination. Intoxicated individuals are high-risk patients.
- Most patients with minor head trauma can be discharged from the ED after a period of observation but require a competent observer.
- Patients sustaining a concussion are at risk for prolonged and substantial morbidity. Athletes should not be allowed to return immediately to sports activities because of the potential risk of second impact syndrome. Most guidelines support a gradual stepwise strategy to have collegiate and high school athletes return to play.

Pediatric Head Injuries

- Children with severe head trauma have fewer intracranial lesions than adults but more edema. In children, increasing edema alone can cause talk and deteriorate or other significant neurologic decline.
- Clinical decision rules such as Kupperman and colleagues[145] algorithm can significantly reduce the number of head CT scans performed on children who experience head trauma.
- Skull fractures have more clinical significance in children than in adults.
- In infants, head injury often occurs from nonaccidental causes. Child abuse should be suspected in young children with head trauma, especially those younger than 2 years of age.

Penetrating Head Injuries

- Tangential gunshot wounds are associated with a high frequency of intracranial traumatic lesions; CT scanning should be performed.
- Anticonvulsant prophylaxis and antibiotics should be given to a patient with penetrating head injuries.
- The clinical outcome after gunshot wounds to the head can be predicted by the initial clinical presentation and the missile path through the brain.

Chapter 42

Facial Trauma

Ryanne J. Mayersak

PERSPECTIVE

This chapter discusses the epidemiology, diagnosis, and treatment of injuries to the skin, soft tissue, and bones of the face. A complex structure vital to the function of the person, the face comprises airway openings, entry to the gastrointestinal tract, and special sensory organs, including eyes, ears, and nose. Facial functioning is essential for eating, speaking, and effective nonverbal communication. The appearance and attractiveness of the face have significant implications for social interactions,[1,2] sexual attraction,[3] and self-esteem.[4] In one study, patients who had sustained facial trauma experienced long-term sequelae including unemployment, incarceration, marital difficulties, and negative body image.[3a]

Apart from immediate threat to the patient's airway and special sense organs, injuries to the face can have serious implications for the patient's mental health[5,6] and future functioning. Post-traumatic patients with facial injuries often describe physical, financial, social, and psychological loss.[7] In one study of predominantly unemployed young African American and Hispanic men, 25% had symptoms of post-traumatic stress disorder 1 month after having been treated emergently for a midface fracture.[5,8,9] Some institutions are now including screening evaluations regarding supportive interventions as well as initiating support groups and online resources for facial trauma patients.[7]

Although the emergency physician's first goal is to address life-threatening problems successfully, the care of facial injuries is aimed at optimizing the patient's function and cosmetic appearance.

Four main specialties—ophthalmology, plastic surgery, otolaryngology, and oral and maxillofacial surgery—participate in the care of facial injuries. In teaching hospitals, the specialties of plastic surgery, otolaryngology, and oral and maxillofacial surgery participate in approximately equal proportions.[10] In level 1 trauma centers, plastic surgeons and oral and maxillofacial surgeons predominate.[11] Early consultation with the appropriate specialist can expedite the care of facial injuries.

Epidemiology

In 2008 there were more than 40 million injury-related visits to U.S. emergency departments (EDs).[12] Facial injuries accounted for a significant proportion of these visits and resulted from either intentional violence (assaults and attempted suicide) or unintentional trauma (falls, sports injuries, and motor vehicle crashes [MVCs]). The type of injury mechanism can be a good predictor of the extent of facial trauma sustained; for example, MVCs were related to multiple facial fractures, whereas assaults more often involved isolated mandibular fractures.[13] Although MVCs used to be the most common cause of facial injuries, windshield improvements, increased use of safety belts, and the prevalence of air bags in vehicles are changing the epidemiology of facial trauma. Dual front-impact air bags have been required in all new vehicles since 1999, and safety belts are required for all passengers in the front row in 49 states (all except New Hampshire).[14] Seat belts and air bags significantly reduce the incidence and severity of facial injury in adults.[15-21] Because they effectively prevent ejection, safety belts specifically avert the extensive scalp and facial degloving injuries associated with being ejected through the windshield.

Alcohol use by vehicle occupants decreases safety belt use and independently increases the risk of facial injury in MVCs.[22] It also increases the risk of interpersonal violence. In one series, alcohol played a role in 49% of all maxillofacial fractures in patients requiring subspecialty care. Of the fractures related to alcohol use, 78% were a result of interpersonal violence and 13% of MVCs.[23,24] Interpersonal violence is increasingly cited as the cause of facial injury, particularly in inner-city populations.[25-28] Falls, dog bites, some athletic activities, and flying debris are other common causes of facial injuries.

Because of the lack of external protection, facial injuries are common among riders of other motorized vehicles, particularly those who are not wearing helmets with face guards, including all-terrain vehicles (ATVs) and motorcycles. In one series in Alabama, 32% of injured ATV riders had a facial injury, and the presence of a facial injury was associated with increased overall injury severity.[29] Among the youngest riders, facial injuries predominate: 31.1% of 0- to 5-year-olds injured while riding an ATV required emergency treatment for a facial injury in 2001 through 2003, although multiple safety and medical groups recommend no ATV use by people younger than age 16 years.[30]

In motorcyclists, there is a significant association between facial injury and brain injury.[31] Helmets reduce the risk of brain injury but may not protect against facial trauma unless they include a face guard.[32]

Unfortunately, a separate group of the injured must now be considered: combat veterans. A review of injuries sustained in battle by combatants in Operation Iraqi Freedom and Operation Enduring Freedom and treated by U.S. military medical facilities for at least 72 hours revealed that 19% of patients sustained injuries to the face, ears, or eyes. Of all these injuries, 19% were caused by gunshots, 79% by explosive devices, and 2% by MVCs.[33]

In children younger than age 17 years, sports injuries account for 21% of facial and 29% of nasal fractures requiring specialist evaluation.[34,35] Baseball and football helmets with face guards are successful at preventing childhood facial injuries, and their use should be encouraged by emergency physicians.[36] Children younger than age 6 years seem to be at significant risk

www.ketabpezeshki.com 66485457-66963820

for severe facial injuries from bites from the family dog.[37] Interactions between pet dogs and young children require careful supervision.

Facial injuries are a common acute presentation for victims of domestic violence. In one series, 81% of domestic violence victims had maxillofacial injuries on presentation, 30% of them with facial fractures. The location of the injury was consistent with the predominance of fisted assaults; left-sided injuries predominated.[38,39] Women visiting the ED with facial injuries should be interviewed privately to allow an opportunity for disclosure and intervention for domestic violence.

Pediatric facial injury accounts for less than 10% of all facial trauma, and the face is the most common area of trauma in children suspected of being victims of abuse.[40] However, the epidemiology of facial trauma among children reflects their physical development and behavioral patterns: toddlers learning to walk have a "falling zone" of trauma to the perioral region, nose, and forehead. Younger children are significantly more likely to have minor soft tissue injuries and to have been the recipient of a dog bite. Severe facial injuries in all pediatric age groups are more likely to be the result of an MVC or assault.[41] Care should be taken by the emergency physician to correlate the child's age and behavioral ability with the history of the injury and the physical findings. In particular, injuries to the lips or frenulum in a nonambulatory infant suggest "bottle jamming," and bruises to the cheeks or neck are less common in falls. Although dental fractures in young children are relatively common, facial fractures before age 5 years are rare. If there is any question, the appropriate local authorities are contacted.

Even in high-energy MVCs, appropriate use of child safety restraints protects against many facial injuries. The law in all 50 states requires the use of such restraints for children younger than age 4 years, and currently 48 states require booster seats until at least age 7 years and many beyond that age.[14] Children younger than age 15 years involved in frontal crashes or exposed to a deploying frontal impact air bag had a higher incidence of minor facial and chest injuries and severe upper extremity injuries, mostly related to being struck by the bag.[43] As part of preventing facial trauma, parents should be encouraged to ensure that children younger than 12 years ride in the rear seat of the vehicle and that all are properly restrained.

PRINCIPLES OF DISEASE

Anatomy

The face is a complex hollow space encapsulated by a bony structure overlaid with muscle and skin. It includes several special sensory organs: the eyes, ears, nose, and mouth.

Bones

The posterior portions of the face form the anterior wall of the calvaria, placing the face and its features in an intimate relationship with the structures of the central nervous system. The anterior facial skeleton is composed of the frontal bone, nasal bones, zygomata, maxillary bones, and mandible (Fig. 42-1). The sphenoid, ethmoid, lacrimal, vomer, and temporal bones lie deep within the facial structure, providing support and important sites for muscular attachments, including the muscles of mastication, speech, and deglutition. This musculature is innervated by cranial nerves IX and X.

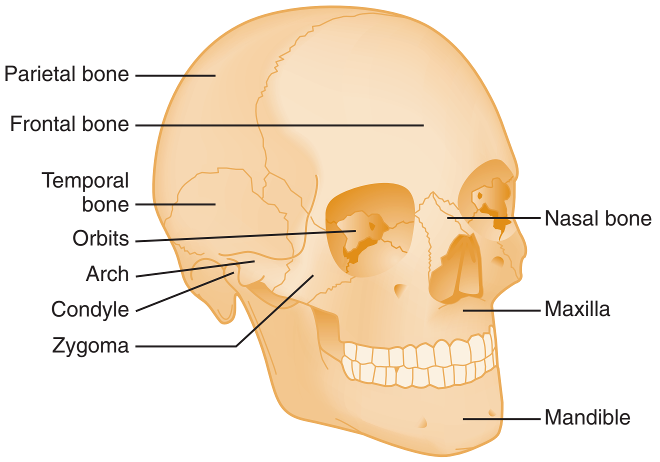

Figure 42-1. Bones of the facial skeleton.

Nerve Supply

The most anterior muscle layer includes the muscles of facial expression that are innervated by the seventh cranial nerve, which lies just inferior to the external auditory canal. The trigeminal nerve (cranial nerve V) supplies sensation to the face through three major divisions (I-III). The ophthalmic division (cranial nerve V1) supplies the upper third of the face, including the eye and the nose down to the tip. The maxillary division (cranial nerve V2) provides sensory innervation to the midface and includes the infraorbital nerve. The mandibular division (cranial nerve V3) supplies sensation to the lower third of the face.

Ears

The ears lie laterally along the sides of the face with the auditory canal exiting through the mastoid process of the temporal bone. The skeleton of the pinna is cartilage covered in closely apposed skin and rolled into a helical shape with a second ridge, the antihelix, defining the inner concha. The external auditory canal, middle ear, cochlea, semicircular canals, and superior origin of the eustachian tube all lie within the temporal bone.

Eyes

The structure of the globe and surrounding ocular musculature is discussed in detail in Chapter 71. The bony orbit is composed superiorly of the frontal bone. The zygoma forms the lateral wall and lateral floor of the orbit. The medial floor and anteromedial wall are formed by the maxilla. The lacrimal and ethmoid bones complete the medial wall, where the orbit is at its most delicate. The medial wall of the orbit forms the lateral walls of the intranasal space.

Nose

The nose serves as a major entryway for air and is composed of cartilage and bone covered by skin with mucosa lining the internal surface. Alar cartilage arches over the entrances to the symmetrical, mucosa-lined nares, separated by the anterior cartilage of the septum. Superiorly, the nasal bones create the bridge of the nose. With the head held in a neutral upright position, the floor of the nose is perpendicular to the ground and leads back into the nasopharynx, passing the turbinates laterally and the bony septum medially. The ethmoid bone lies superiorly and crosses midline, behind the nasal bridge, to form the superior portion of the bony nasal septum and the cribriform plate. The vomer makes up the inferior portion of the bony septum, and the palatine process of the maxillary bone forms the posterior floor of the nose and the hard palate.

www.ketabpezeshki.com 66485457-66963820

Air-containing sinuses are structural features unique to the facial skeleton. They warm and humidify inhaled air and form chambers that create the unique tone of human voices. These sinuses develop over the period of human growth. At birth, only the ethmoid air cells and the mastoid antrum are aerated. The sphenoid sinus and the remainder of the mastoid air cells become aerated at approximately age 3 years. Frontal sinuses form at approximately age 6 years, and maxillary sinuses are not fully developed until age 10 years.

Mouth

The mouth serves as an entryway for the respiratory and gastrointestinal tracts. In addition, the fine motor movements of the mouth and tongue give humans the ability to communicate through speech. With the mouth in the closed position, the tongue fills the oral cavity. Single rows of teeth lie within the alveolar ridges of the maxilla and the mandible. With the mouth closed, the teeth in normal individuals occlude, with the lower row lying just internal to the upper row. The "usual" occlusion for individuals varies widely; the patient's perception may be the best determinant of whether or not the teeth are meeting as usual. Anterior to the teeth is the vestibule, a fold of mucosa and flexible soft tissue that allows the lips to remain closed while various motor movements occur behind them. The mandible is a U-shaped bone that forms the chin and completes the lower facial skeleton. Containing the lower row of teeth, the body of the mandible meets in midline at the symphysis, which is completely fused by age 2 years. Posterior to the last molar, the bone turns to form the angle of the jaw and continues upward as the ramus of the mandible. At the most superior point of the ramus is the articular surface of the condyle, separated from the superior surface of the temporomandibular joint (TMJ) by an intervening meniscus of fibrocartilage. Anterior to the condyle lies a thin projection, the coronoid process, which provides the insertion point for the temporal muscle.

The skin of the face is among the thinnest of the body, draping over the underlying musculature. Facial skin falls visibly into predictable creases with age, following Langer's lines (Fig. 42-2). At the mouth, nares, and palpebral fissures, the skin is contiguous with the mucosa lining these structures. The skin of the lips is particularly thin and lined with vascular papillae, which give the lips their vermilion hue. Lips are particularly important as part of communication; understanding their movement can allow language without sound (lip reading).

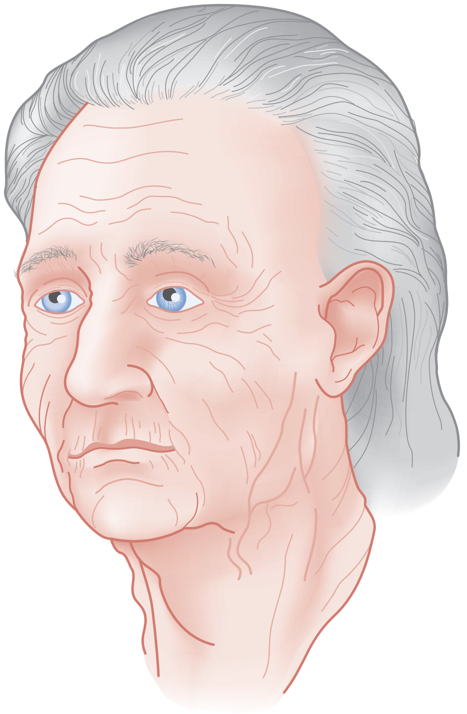

Figure 42-2. Langer's lines: lines of facial expression.

The face is a highly vascular structure; this can have grave implications for the treatment of facial injuries. With the exception of the ophthalmic artery, the superficial blood supply comes from the external carotid artery via the facial, superficial temporal, and maxillary arteries (Fig. 42-3). Soft tissue injuries and fractures that involve these vessels can lead to significant hematomas or exsanguinations. Because the face has extensive anastomotic connections across the midline and between arterial territories, however, ligation of major branches causes minimal ischemia.

Buried within the structure of the face are a series of glandular structures and ducts that are susceptible to injury. In the eye, the lacrimal glands lie within the orbits, superior and lateral to the globes, and secrete tears through ductules into the folds of the conjunctiva. The liquid flows medially into the puncta of the lacrimal canaliculi and drains into the lacrimal sac and then via the nasolacrimal duct into the nasopharynx.

The salivary system consists of the parotid, sublingual, and submandibular glands. The parotid is the largest of these glands, lying just anterior to the ear and wrapping around the mandible. The parotid is superficial to the masseter muscle and drains via Stensen's duct, a 5-cm tube that curves around the anterior edge of the masseter to enter the mouth opposite the second upper molar. In normal subjects, this duct is large enough to be palpated with the masseter clenched (Fig. 42-4). The sublingual glands lie entirely within the floor of the mouth and drain into the mouth via ductules. They surround the ducts draining the submandibular glands (Wharton's ducts). The body of the submandibular gland is folded around the mylohyoid muscle so that a portion lies within the floor of the mouth and a portion lies external to it. The submandibular (Wharton's) ducts run from the external portion of the gland to empty into the mouth on either side of the frenulum of the tongue.

Pathophysiology

The basic mechanism of all injury is the transfer of energy, most often kinetic, to the structures of the body. When the energy overcomes the tolerance of the underlying tissue, injury results. Trauma traditionally has been classified as blunt or penetrating, but in many cases the effect is a combination of the two, such as the forehead injury (contusion and complex laceration) resulting from a child's fall against the sharp corner of a coffee table. The likelihood of injury is related to the amount of energy transferred and the condition of the underlying tissue. Significant injury may result when an 80-year-old falls from standing to a carpeted floor, but it is more likely to result when the face strikes the steering wheel or dashboard in a high-speed MVC.

The mechanism can be broken down into *low-energy* events, such as a fall from standing or walking into the corner of a piece of furniture, and *high-energy* events, such as an MVC. Understanding the mechanism of injury can help predict not only the severity of the facial injury but also the risk of associated cervical or brain injuries.

Traditional teaching has been that the face protects the brain from injury and that patients with facial trauma are less likely to have a significant brain injury. This does not appear to be correct. Instead, recent work suggests a significant increase in risk for brain injury among blunt trauma patients with facial fractures.[44]

The association between cervical injury and facial injury is unclear. The traditional teaching has been that the presence of a facial injury should increase the suspicion of an injury to the

www.ketabpezeshki.com 66485457-66963820

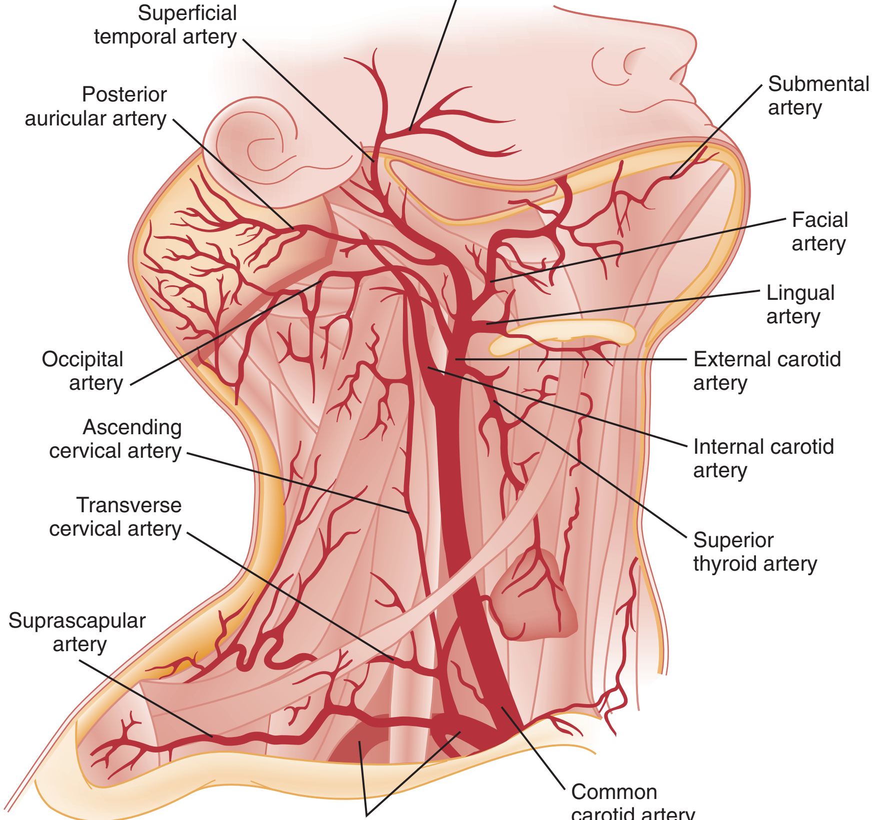

Figure 42-3. Vessels of the face. (Redrawn from Gray H: Gray's Anatomy, Philadelphia, Lea & Febiger, 1918.)

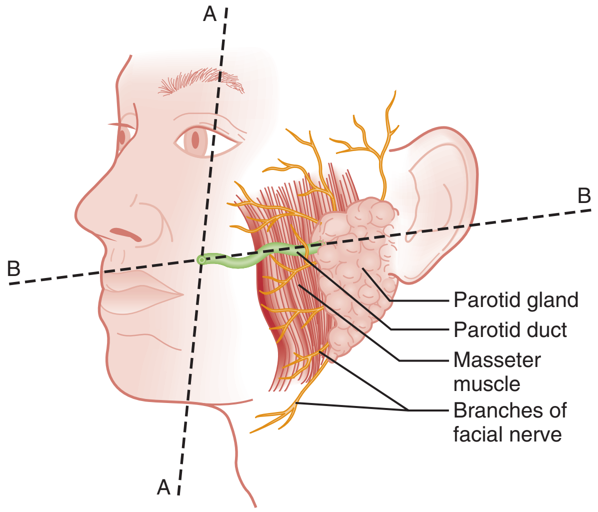

Figure 42-4. Parotid gland and duct (Stensen's) with the surrounding branches of the facial nerve. Line B approximates the course of the duct, which enters the mouth at the junction of lines A and B.

cervical spine. However, most of the studies supporting this idea are assessments of the incidence of cervical spine injury in patients with facial injury.[45] When more sophisticated methods are used to assess any association between the two while correcting for the mechanism of injury, patients with facial injury appear to be less likely to have a significant cord injury, and there is no relationship with bony spinal injury.[46] Thus in a particular patient, cervical and brain injuries should be considered based on the mechanism of injury and presentation of the patient without allowing the presence or absence of a facial injury to change the level of suspicion.

Penetrating trauma to the face from gunshots, stab wounds, blast debris, or impalement is often obvious and dramatic (Fig. 42-5). The astute emergency physician should search avidly for associated intracranial, spinal, or vascular injuries, which are common in these cases.[47] Facial penetration from pellets (BBs) or small blast debris or shrapnel may be less obvious, and the emergency physician should be alert to the possibility based on the history and should carefully search for small skin lesions.[48] Recreational hobbies such as paintball and new law enforcement weapons such as the "flash ball," which can have substantial kinetic energy, have caused significant facial and upper body trauma.[48a,48b]

CLINICAL FEATURES

History

The history can provide information about the mechanism of the patient's injury. The emergency physician, however, should be alert to limitations of the history in cases in which the patient's consciousness is altered by head injury or intoxication, there is an issue of secondary gain, the police are involved, or abuse is suspected. Patients with a clear sensorium are able to describe the events leading up to the injury and localize pain; deficits in motor or sensory function; and abnormalities of vision, hearing, taste, or

www.ketabpezeshki.com 66485457-66963820

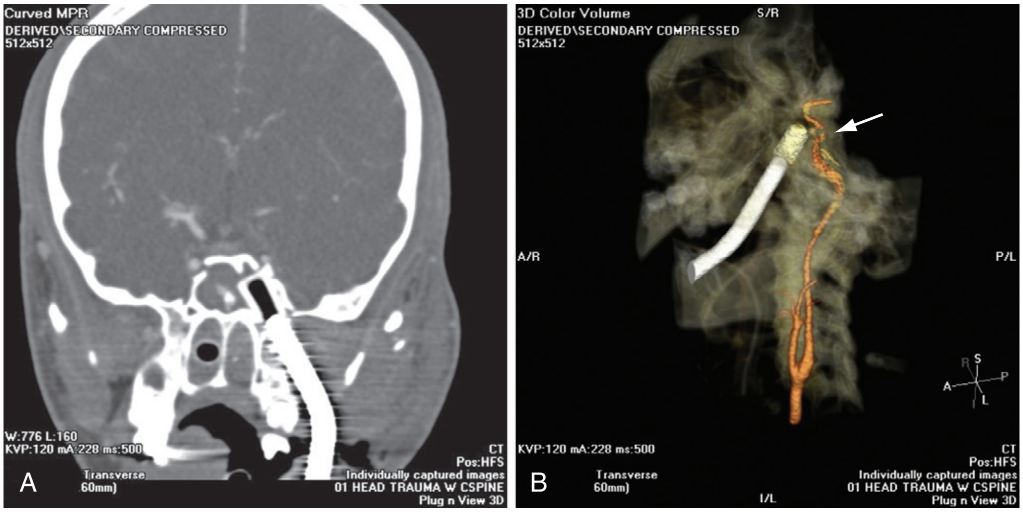

Figure 42-5. Impalement by a turn-signal lever. Computed tomography **(A)** and three-dimensional reconstruction **(B)** from a patient impaled through the face into the cranial cavity by the turn-signal lever from his steering column when his vehicle rolled over in a single-car crash. The color three-dimensional reconstruction reveals a significant injury to the facial artery *(arrow)*.

smell. Although the association between facial trauma and brain or cervical spine injury is unclear, these possibilities should be considered, and the patient should be questioned regarding headache, peripheral weakness, numbness, or paresthesias.

Physical Examination

Many facial injuries can be identified by simple inspection. During the primary assessment, attention is initially on the patient's airway, and inspection of the oropharynx is an essential first step. Airway compromise is often a result of intraoral trauma, and the examiner should note excessive bleeding, drooling, dysphonia, swelling of the tongue or posterior pharynx, and the presence of avulsed teeth. When the patient is stabilized, a secondary survey should include a systematic examination of all facial structures and functions. Bony prominences should be palpated for abnormal motion, bony crepitus, tenderness, or step-off. Tenderness and massive swelling associated with facial trauma may preclude reliable palpation of a fracture. Consequently, areas of significant swelling should be imaged radiographically. Assessment of bony integrity includes testing for possible Le Fort fracture. The upper incisors are grasped and pulled anteriorly. Movement of the upper alveolar ridge (type I), midface (type II), or entire face (type III) indicates a fracture. Wounds may need to be palpated for underlying bony injury or foreign objects; anesthesia may be required for a thorough examination within the wound. Complex lacerations involving the cartilage of the nose or ear, eyelids, lacrimal apparatus, eyebrows, or vermilion border of the lips should be identified because their repair requires special techniques.

Eyes and Orbits

In addition to examination of lacerations and contusions, the face should be evaluated for symmetry. The appearance of the zygomata may be evaluated by looking at the patient from above. This technique also draws attention to the relative position of the eyeballs. Orbital fractures may result in enophthalmos, and a large retrobulbar hematoma may cause exophthalmos. The anterior chamber of the globe should be inspected for hyphema or globe rupture. A hyphema is caused by bleeding in the anterior chamber and appears as a layer of blood in the dependent portion of the anterior chamber. A complete examination of the eye requires specific testing. If the patient is able to cooperate, visual acuity should be documented. Contact lenses should be removed. In the event of a significant potential chemical exposure, the pH of the eye may need to be measured. Fluorescein examination of the eye should be performed if there is any concern about corneal abrasion. Victims of MVCs often have particles of glass in the conjunctiva or on the cornea, and these should be sought and removed. Extraocular motions should be tested. Blow-out fractures of the orbit may result in diplopia on upward gaze secondary to entrapment of the inferior rectus muscle or anesthesia of the midface and upper lip in the distribution of the second division of the fifth cranial nerve secondary to neuropraxia resulting from a fracture through the infraorbital foramen or compression by a local hematoma.

Oropharynx

The integrity of the mouth and nasal complex may be evaluated by listening to the patient's speech. A muffled or overly nasal voice may indicate occlusion of the nose or nasopharynx, whereas dysarthria may indicate a mandibular fracture, tongue injury, or neurologic problem. Oral injury may result in progressive airway compromise, and dysphonia should alert the clinician to the possible need for active airway management. The intraoral examination includes inspection of the palate, teeth, tongue, and gums and palpation with a gloved finger (the latter only if the patient is able to cooperate). The range of motion of the mandible should be determined. If the maximal incisor opening is less than 5 cm, a mandibular fracture may be present. Trismus is likely to indicate a fracture or significant hematoma within the face. If awake, the patient's impression about the normalcy of bite occlusion is a more sensitive determinant of a fracture of the mandible than the physician's impression. Being able to perform a tongue blade test (grasping and holding a tongue blade between the teeth while the examiner pulls gently) is associated with greatly reduced probability of mandibular fracture. If the patient is able to crack the tongue blade by biting on both sides of the mouth, the negative predictive value for a mandibular fracture is 95%.[49] Injury to the parotid area should raise suspicion of disruption of Stensen's duct. The opening of the duct opposite the second upper molar should be examined for bleeding while the gland is compressed. If blood

www.ketabpezeshki.com 66485457-66963820

is expressed from the duct or the severed ends of the duct are identified within a facial wound, specialized repair over a stent is required to prevent formation of a cutaneous fistula.

Ears

Otoscopy is performed to evaluate the integrity of the external canal, look for hemotympanum, and assess for otorrhea. Clear fluid from the ear after trauma should raise the possibility of a cerebrospinal fluid (CSF) leak. At the bedside, a drop of the fluid may be placed onto filter paper. A rapidly advancing halo of clear fluid around red blood defines a positive test result. This is a quick bedside test with good sensitivity (>86%) as long as the mix is approximately 50:50 between blood and other fluid, but it does not differentiate between CSF and saline, saliva, or other clear fluids.[50]

The ear should be inspected for subcutaneous hematomas because these need to be drained.

Nose

The nose is palpated for tenderness, crepitus, or abnormal movement, and then each naris is held closed in turn to ensure the patient is able to breathe through either side. The septum should be examined visually to look for septal hematoma, which appears as a large purple mass extending from the septum. If there is any concern about CSF rhinorrhea, the aforementioned filter test may be performed.

Neurologic Examination

Light touch should be tested for all three branches of the fifth cranial nerve. Motor function (cranial nerve VII) can be examined by having the patient actively wrinkle the forehead, fully open and close the eyelids, smile widely, and bare the teeth. Asymmetry of these movements indicates a potential nerve injury. Peripheral injuries to the seventh cranial nerve should cause discernible weakness in the forehead as well as the orbital and oral musculature, whereas central injuries will result in preserved forehead function because of crossing fibers distal in the course of the nerve. The fifth cranial nerve (the ophthalmic branch of the trigeminal nerve) and the seventh cranial nerve in an altered or uncooperative patient can be assessed by testing the corneal reflex.

The final part of the physical examination is documentation. Facial injuries may be evidence of assault, domestic violence, or child abuse. Careful documentation of findings, including photographs or drawings or both, not only communicates initial findings to other practitioners but also can provide crucial legal evidence because many of these cases have forensic implications or result in litigation.

DIAGNOSTIC STRATEGIES

Imaging

The choice of imaging for facial fractures depends on the patient's stability, the patient's ability to cooperate, and the availability of various options. The two main options are plain x-ray examination and computed tomography (CT). Fractures are better visualized with CT than with magnetic resonance imaging, so magnetic resonance imaging is not an optimal imaging choice. In patients who cannot cooperate for plain x-ray examination or in whom a fracture or penetrating injury is obvious from the physical examination, CT is the imaging modality of choice.[51] For a complete evaluation, CT scans of the face should include coronal and sagittal reconstructions. Interpreting facial CT scans is an art that requires attention to bones, sinuses, orbital contents, and soft tissue and is best handled by radiologists.

With the increasing use of CT in emergency medicine and the advent of telemedicine, most 24-hour EDs have access to CT scanners for facial injuries. CT is now the first choice for all patients in whom a midface fracture is suspected. However, when no scanner is available and in patients with low to moderate pretest probability of a midface or maxillary fracture and who are stable and able to cooperate, the current recommendation is for a single screening view (Water's or occipitomental view), followed by CT if the film is positive for a fracture or air-fluid level in any sinus.[52-54]

The U shape of the mandible and the presence of nearby bony structures make isolating the mandible on flat film impossible. Simple radiographs of the mandible are less sensitive than panorex radiographs and particularly tend to miss fractures of the condyle (Fig. 42-6). If available, panorex imaging is indicated for isolated mandibular fractures, dental fractures, or fractures of the alveolar ridge. In children, if fracture of the condyle is suspected, coronal CT is more sensitive and specific than panorex studies.[55] Although the traditional teaching has been that the mandible's shape results in two fractures if it is fractured at all (Fig. 42-7), a case series using CT evaluation found that 42% of mandibular fractures were unifocal.[56]

For patients with complex fractures, new imaging techniques may help improve surgical planning and esthetic outcomes. In displaced orbital fractures, use of CT data to measure orbital

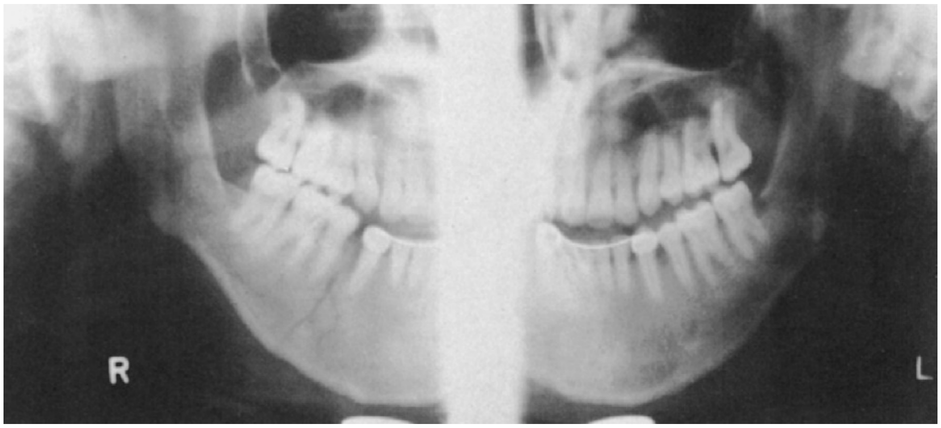

Figure 42-6. Panoramic radiograph of the mandible shows fractures through the left angle and the right body. A dental appliance is in place on the lower incisors.

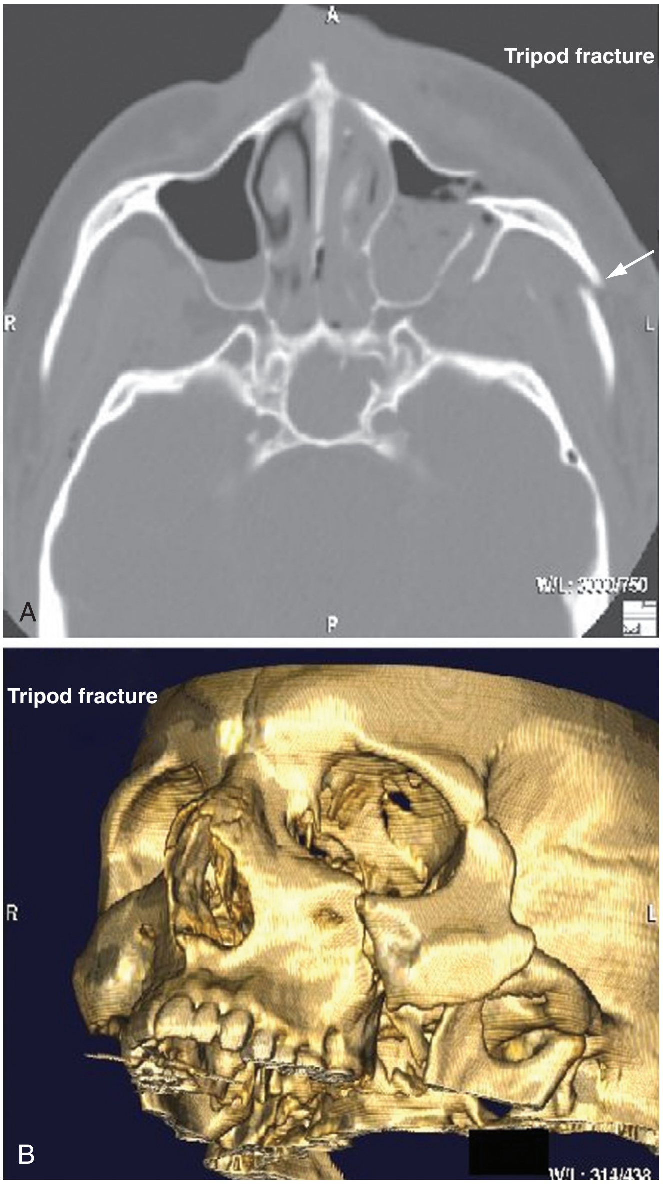

Figure 42-8. Tripod fracture. Computed tomography (**A**) and three-dimensional reconstruction (**B**).

volumes has shown that after repair an orbital volume greater than 4% larger than on the unfractured side is associated with visible postoperative enophthalmos.[57] This method seems to be useful in predicting which patients might benefit from operative repair.[58] In conjunction with more standard two-dimensional facial CT scans, three-dimensional CT scans seem to improve the diagnosis and aid preoperative planning for patients with complex fractures of the midface (Fig. 42-8B).[59-62]

Patients with tenderness and swelling isolated to the bony bridge of the nose who do not have a septal hematoma, can breathe through each naris, and have a straight nose do not require nasal bone radiographs in the ED because imaging results would not alter treatment. If these criteria are not met, early reduction or referral for surgical intervention may be indicated, and plain films (for truly isolated injuries) or CT scanning (if concern for other injuries exists) is indicated. Plain x-ray examination may also be performed in the setting of legal concerns. If there is concern for a foreign body in a superficial wound, two standard x-ray views (Water's and Caldwell's or occipitofrontal view) are indicated to triangulate the position of the observed foreign material.

Patients with suspected ocular injuries may benefit from a bedside ultrasound as a noninvasive and economical diagnostic tool, particularly if there is a need for urgent operative management of other injuries and no time for a dedicated facial CT. The different acoustic impedances of the orbit's anatomic structures make the modality operator friendly, and an ultrasound of the eye can readily detect vitreous hemorrhage, retinal detachment, and globe rupture (Figs. 42-9 and 42-10). The operator should position the transducer in a transverse orientation, scanning in a cephalad-to-caudad direction, making sure to scan the entire anatomy of the eye, and using special care to minimize the pressure exerted over the eye, especially when evaluating for specific ocular emergencies. Prior findings have suggested that high-resolution ultrasound has at least a 94% correlation with axial and coronal CT imaging in the detection of orbital fractures and emphysema.[63,64]

MANAGEMENT

Management of facial injuries occurs within the overall resuscitation of the patient. Unless the airway is threatened or exsanguination is a concern, treatment of most facial injuries can be deferred until more life-threatening injuries have been stabilized. Care of the patient with penetrating trauma to the face should center

www.ketabpezeshki.com 66485457-66963820

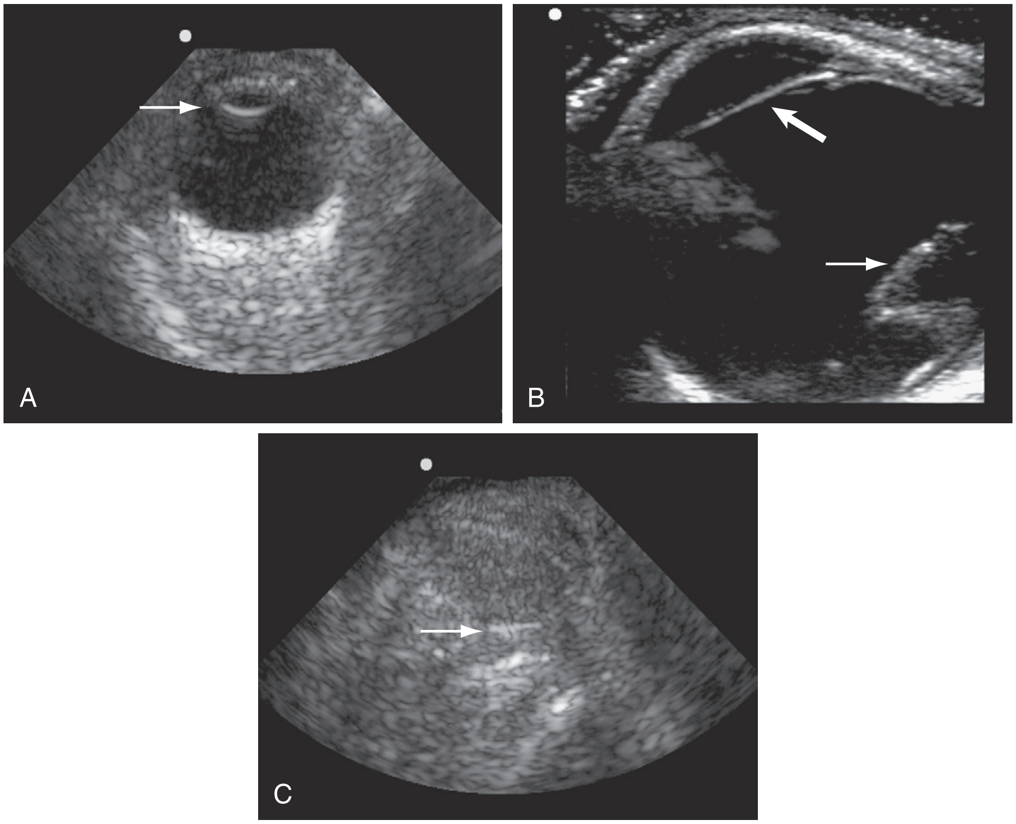

Figure 42-9. Bedside sonograms of the eye. In each image, a small white dot is placed to identify the front of the eye, and thin arrows identify the lens. Sonogram **A** demonstrates a normal eye. on standard trauma care, with initial attention focused on maintenance of a patent airway, adequate ventilation, and systemic perfusion.

Out-of-Hospital Care

The indications for airway management of a patient with a facial injury are the same as those for other patients: Does the patient have a currently patent airway and, if so, can the patient be expected to maintain it without intervention? If the answer to either question is “no,” the patient needs to be intubated. If other injuries preclude the patient from ventilating appropriately, intubation is also required.

Patients with expanding hematomas after facial injury present a special dilemma. Injuries to the facial vasculature may cause significant hematomas that can extend into the neck or down to the supraclavicular area. Such hematomas greatly distort the normal anatomy of the pharynx and neck, making intubation and cricothyroidotomy particularly difficult. If the patient has a patent airway, he or she can speak without difficulty, and the transport time is expected to be short, no intervention should be performed and the receiving institution should be notified so that planning can begin for a difficult airway. If intubation must occur in the field, awake orotracheal intubation should be considered. If certified in its use, emergency medical services personnel should be ready to perform a surgical airway as needed. Gunshot wounds to the lower third of the face are particularly likely to require intubation for airway protection, and a significant proportion of these require a surgical airway.[65]

In the setting of significant facial trauma, active bleeding can obscure the view and make intubation considerably more difficult.

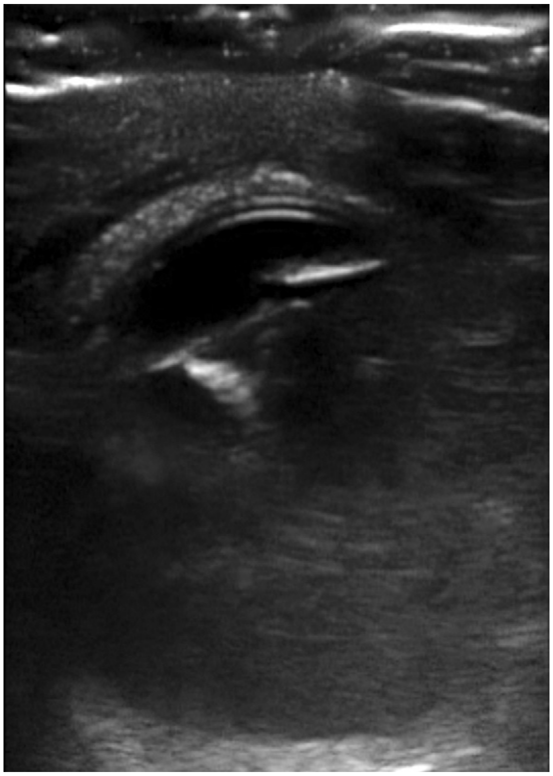

Figure 42-10. Ultrasound image of a globe rupture with lens dislocation. At the top of the image the cornea is visible, and just below that is the dislocation with hemorrhage visible posteriorly.

www.ketabpezeshki.com 66485457-66963820

Double suctioning may be required, which involves an assistant holding one suction catheter in the posterior oropharynx while the operator uses a second device more anteriorly or inferiorly as needed during the procedure. Conversely, patients with fractures of the mandible may be easier to intubate because increased mobility of the mandible may allow wider opening of the mouth.

Blind nasotracheal intubation is controversial in the literature and is rarely indicated in facial trauma because of concerns about complications.[66] Patients with multiple injuries who require intubation may not be breathing actively enough for this method to be of use, and out-of-hospital rapid sequence intubation is associated with a higher success rate and fewer complications.[67] Some alternative airway techniques may include submental or submandibular intubations or anesthesiology-assisted intubations with the use of adjuncts such as the GlideScope or lighted stylet.[67a,67b] Although reports of intracranial placement of an endotracheal tube in facial trauma are rare, this catastrophic complication is known to occur after blind nasotracheal intubation.[68,68a] Any concern about an injury to the skull base or cribriform plate is a contraindication to this method of intubation.

Control of local bleeding is the other significant out-of-hospital consideration in facial trauma. In many areas, external compression is sufficient to control bleeding during transport. Epistaxis and significant intraoral bleeding can be more difficult to treat. Even in the setting of significant nasal trauma, the soft portions of the nares can be compressed to stop anterior nasal bleeding. In an awake, alert patient with intraoral bleeding, 4 × 4-inch gauze packing may be placed into the buccal space to provide control. If these maneuvers are insufficient and the patient's injuries require spinal immobilization, intubation may be a necessary first step to control intraoral or nasopharyngeal bleeding. After intubation, large amounts of gauze can be placed via the mouth into the oropharynx and nasopharynx to obtain control via direct pressure.

If out-of-hospital personnel suspect a ruptured globe, special protection against compression of the eye (eye cup or noncontact shielding) should be provided in the field. Avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed flaps, should be transported with the patient in saline-soaked gauze.

Completely avulsed teeth should be removed and carried with the patient during transport. Neurologically normal, unintoxicated patients may be able to carry avulsed teeth in their mouths, held between gum and buccal mucosa. Patients who are not neurologically normal, who are intoxicated, who require cervical spine immobilization, who are nauseated, or who cannot be transported upright should not be transported with avulsed teeth held in the mouth. In such cases, the risk of aspirating the teeth outweighs any other concerns, and the teeth should be transported in a container with sterile saline. Incompletely avulsed teeth should be left in place and not manipulated.

General Measures

The initial evaluation in the ED should readdress the question of intubation. In the setting of significant distortion of the mouth, oropharynx, or upper neck by avulsion or hematoma, the awake fiberoptic method may optimize the chances of a successful intubation. When there is significant distortion of the oropharynx or larynx, a laryngeal mask airway may not achieve a sufficiently tight fit to allow ventilation. Emergent cricothyroidotomy is the procedure of choice if endotracheal intubation is impossible.

Unless there is life-threatening hemorrhage from the face, after the airway has been secured, facial injuries can be safely left to the secondary survey. The emergency physician should avoid being distracted by a facial injury and search intensively for head, neck, chest, abdominal, pelvic, and extremity injuries. In-depth ocular examinations and other special testing should not be performed until other serious injuries have been managed emergently.

Significant bleeding can often be controlled by compression. If compression fails, hemostasis can be achieved in the ED by ligation of the relevant vessel. Great care should be taken, however, not to clamp or tie structures blindly deep within the face because serious iatrogenic injury of nerve or ductal structures could result. Massive, uncontrollable bleeding from facial fractures occurs rarely and is best treated with arterial embolization, if available.[69,70] Intra-arterial vasopressin has recently been suggested as an option for hemostasis.[71]

In the rare case of a patient acutely exsanguinating from a facial wound, the external carotid artery can be emergently ligated. This ligation is best accomplished with surgical assistance.

Bite wounds, gross contamination, or significant tattooing from foreign bodies should be addressed definitively as soon as possible, given the needs of the patient's other injuries. Definitive treatment of simple soft tissue injuries can be left for 24 hours, if needed, after irrigation and temporary approximation. Ideally, facial fractures are treated early, before significant swelling occurs, or after several days when return of more normal facial contours can aid in the repair. The need for tetanus prophylaxis should be considered for all open wounds. If the injury is an animal bite, the need for rabies prophylaxis should be considered. Because the rabies virus is transmitted to the brain along nerve axons, and symptomatic disease theoretically may occur sooner with wounds of the head, face, and neck, initiating rabies treatment within 5 days of the injury is recommended.

Finally, because lead poisoning has been reported from the ingestion of shotgun pellets in patients with primarily facial injuries, consideration should be given to looking for the presence of pellets in the gastrointestinal tracts of these victims. A plain x-ray film of the abdomen suffices. Early endoscopic removal of the pellets should limit future toxicity.[72]

Soft Tissue Injuries

Soft tissue injuries to the face present an acute cosmetic concern for the patient. Areas may be contused, lacerated, abraded, or any combination of the three. When cleaned of any debris, abrasions may be covered in a thin layer of antibiotic ointment and left exposed or covered (as possible given their location). Patients with significant tattooing will benefit from topical lidocaine for anesthesia before vigorous scrubbing is begun to remove the embedded material. Careful attention should be paid to removing all of the embedded material as soon as possible because epithelialization requires the creation of a new wound to remove debris later. For contusions, ice and sleeping with the head elevated may limit the degree of swelling anticipated on days 2 and 3. The patient should be cautioned to anticipate the development of periorbital swelling or ecchymosis or both over time as a result of gravity when the primary contusion has been to the brow, forehead, or bridge of the nose.

The most appropriate person to close an open wound may be either the emergency physician or a consultant. Decisions about which wounds to close personally and which to ask a consultant to repair are based on the personal judgment of the emergency physician. Factors that may be considered in the decision include resource availability; the size, shape, depth, and location of the wound; and the time commitment that careful, cosmetic wound closure can entail for the emergency physician in a busy ED. The patient's priority with facial lacerations is cosmesis, and therefore a patient may request specialty services for even minor wounds.[73] Children and patients with behavioral problems may require

www.ketabpezeshki.com 66485457-66963820

sedation to allow sufficient control for a cosmetic repair. Repair of facial wounds in uncooperative patients who are acutely intoxicated may be delayed until they become sober enough to cooperate for the procedure.

After anesthesia has been achieved, wounds should be explored for depth, foreign bodies, and underlying fractures. Irrigation may not be necessary in simple, clean facial wounds closed within 6 hours.[74] For nongaping wounds less than 3 cm, a single-layer closure may be sufficient.[75] For gaping wounds deeper than the dermis, subcuticular buried sutures of absorbable materials should be placed to close any potential space and relieve any tension on the skin. For skin closure, tissue adhesive is faster and less painful, results in equal cosmetic results in adults and children, and can be used to close the skin over deeper sutures.[76,76a] Compared with sutures, tissue adhesive has the additional benefit of not requiring later removal, but care must be taken not to unintentionally glue the eye, nares, or mouth closed.

Antibiotics are not required for simple facial wounds, which rarely become infected. Bite wounds, wounds with any evidence of devascularization, wounds through and through the buccal mucosa, wounds involving the cartilage of the ear or nose, and wounds with extensive contamination (particularly with barnyard or fecal matter) are exceptions to this rule.

The choice of antibiotic therapy will likely be an evolving topic in light of the emergence of community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA). Among spontaneous skin infections requiring an ED visit, the prevalence of CA-MRSA is now quite significant for both adults and children.[77-79] In addition, it appears that the incidence of such spontaneous infections requiring ED care is also increasing.[78] However, current literature does not suggest choosing antibiotics with MRSA coverage for wound prophylaxis. If prophylactic antibiotic therapy is needed, the antibiotic should be selected based on the normal bacterial flora associated with the affected site.[80,81]

SPECIAL CONSIDERATIONS BY SITE

Mouth

Lacerations

Lip lacerations are common and require special consideration to maintain the appearance of the lip edge or vermilion border and the natural architecture of the philtrum. Because infiltration of even a small volume of local anesthetic may distort and blanch the soft tissue, marking the vermilion border (with nonpermanent ink or a scratch of a sterile needle) before anesthesia facilitates a cosmetic repair. To minimize any divots and maximize cosmesis and function, wounds that include the muscular layer should be closed in multiple layers. Skin may be closed with nylon or other nonabsorbable suture; the lip and mucosa should be closed with absorbable suture. Lip lacerations are not amenable to closure with wound adhesives.

Through-and-through lacerations of the mouth should be closed in layers, beginning with the intraoral mucosa and working outward in layers toward the skin. After closure of the mucosal layer, copious irrigation of the external wound is indicated to remove lingering bacteria that otherwise would be incorporated into the wound. In small case series, prophylactic treatment with penicillin has been shown to decrease the risk of infection after significant through-and-through lacerations.[82] Lacerations that approach the parotid (Stensen's) or submandibular (Wharton's) ducts should be evaluated before intervention for ductal integrity. Saliva milked from the gland should be thin and clear and should readily exit the duct. If a duct is involved or there is any doubt, a facial specialist should be consulted for evaluation and repair.

Small lacerations of the tongue or oral mucosa do not require repair. Lacerations that gape (including deep tongue lacerations), collect food, and are likely to heal with a significant divot or thick scar that may hinder eating and speaking functions require repair. Deep or gaping lacerations of the tongue or oral mucosa should be closed (in layers if necessary) with absorbable sutures that do not require removal. To facilitate repair, an assistant may be needed to expose the laceration by grasping the tongue between gauze and holding a segment outside of the mouth. Some advocate placing a thick temporary suture through the distal tongue (after appropriate anesthesia) to facilitate this exposure. Discharge instructions for intraoral lacerations (whether or not repaired) should include gentle cleansing (swish and spit) with a mild antiseptic.

Perioral Burns

Young children use their mouths to explore their environment and may lick electrical outlets or bite electrical cords. The wet oral mucosa provides little electrical resistance, and the current penetrates to deeper structures, often causing a full-thickness burn at the commissure of the lip. These children need a systemic evaluation for other electrical injuries (see Chapter 142); this discussion is limited to the evaluation and treatment of facial wounds. Perioral burns resulting from electrical injury can result in severe cosmetic problems and microstomia. The initial appearance of the wound may be misleadingly trivial; edema and necrosis progress over several days, and even with healing the defect may become quite disfiguring. Traditionally, a more acute concern has been bleeding from the labial artery when the maturing burn eschar separates from underlying structures 5 to 21 days postburn, and it was previously recommended that patients be admitted so that such bleeding could be urgently addressed if it occurred. In general, current practice is discharge with close observation at home and follow-up with otolaryngology specialists, plastic surgery specialists, or both to address cosmesis. Large wounds can cause significant early difficulty with eating, however, and patients may require placement of a nasogastric tube for maintenance of nutrition. Initial ED treatment of the wound is aimed at treating discomfort and keeping the area clean.

Treatment of these injuries is controversial; options include conservative treatment with early oral splinting, immediate surgery aimed at reconstruction, or delayed excision of the burned area. Later reconstructive repair may be required to preserve mouth opening, eating, and speech clarity.[83] Early involvement of consultants is indicated, even when the burn seems to be trivial. The possibility of abuse or neglect should be considered when a child is presented with a perioral burn.

Cheeks

Contusions of the cheek should raise concern for an underlying zygomatic or maxillary fracture. Lacerations of the lateral cheek may involve the parotid gland or Stensen's duct. Failure to identify and repair ductal injury results in retention of salivary fluid and enlargement of the gland or formation of a cutaneous fistula. Lacerations in the area anterior to the tragus may include injury to the facial nerve, and careful neurologic examination should be carried out before closure. Langer's lines change from mostly horizontal in the superior cheek to diagonal at the nasolabial fold, then curve convexly around the mouth; these changes should be taken into consideration when débridement is required as part of a complex repair.

www.ketabpezeshki.com 66485457-66963820

Nose

Because of its anterior position, soft tissue injuries to the nose are common. Almost any trauma can result in epistaxis. In general, epistaxis is controllable by pinching the cartilaginous anterior nose closed between two fingers and holding compression for approximately 10 minutes. If it is not controlled, anterior packing is indicated. Intranasal inspection is required in any nasal injury to assess for a septal hematoma, which appears as a dark purple or bluish mass against the septum. Hematomas require drainage because they are associated with necrosis of the septum if left untreated. Simple incision and expression of the clot followed by anterior packing are sufficient. Traditional teaching has been that any patient with nasal packing should receive prophylactic antibiotics to cover *Staphylococcus* and *Streptococcus* species to prevent sinusitis and toxic shock syndrome. Toxic shock syndrome is a rare but measurable complication of postoperative nasal packing, occurring in approximately 16 per 100,000 cases; the incidence with primary packing is unknown.[84] There is no evidence that prophylactic antibiotics change the risk of developing toxic shock syndrome or sinusitis in postoperative or primary packing[85]; the few studies that have been done have had sample sizes far too small to show an effect.

Because of the location and structure of the nasal bridge, fractures of the thin bones of this area are common. Patients with contusion or tenderness over the bridge of the nose may be assumed to have a fracture of the nasal bones. If the nose is acceptably straight on initial evaluation, there is no septal hematoma, epistaxis is controlled, and the patient is able to breathe out of each naris, no further evaluation is required emergently for isolated nasal injuries. Although radiographs of the nasal bones are still in use, they have no clinical utility.[86-88]

Swelling over the bridge often precludes determination of the acceptability of the appearance at the time of injury. The patient may be provided with a referral for outpatient specialty follow-up in 3 to 5 days if the appearance at that time (when the swelling has improved) is unacceptable. In a series of surgically repaired simple nasal bone fractures, septal fractures were present in more than 50% of cases. CT did not provide any advantage in diagnosing septal fractures and should be reserved for evaluating patients suspected of having other, more complex fractures.[89,90]

Children with nasal fractures may have premature closure of sutures and uneven growth, particularly of the vomeroseptal line. In a child, no imaging studies are indicated, but a consultant should evaluate swelling and tenderness over the nose, preferably within 4 days of the injury.[91]

Simple lacerations of the nasal skin may be closed with sutures or tissue adhesive. If needed, anesthesia may be achieved with a nerve block of the infraorbital or supratrochlear nerves. The large pores typically present in the area of the nasal ala increase the likelihood of stitch abscesses after laceration closure in this area. Closure with an absorbable running subcuticular suture may limit the risk of this outcome. If involved, the cartilaginous portions of the ala should be closed in a separate layer with absorbable 4-0 suture. For lacerations through and through the nose, repair should be carried out from the mucosal layer outward, with copious irrigation between layers.

Ears

Blunt trauma to the ear may cause hematoma formation in the subperichondrial potential space. Such hematomas are the prelude to the development of a "cauliflower ear" and should be drained by aspiration. Reaccumulation of the hematoma is prevented with a compressive dressing of the ear, but reexamination is crucial, and reaspiration should be performed as necessary.

Ear lacerations often involve the cartilage. The ear may be anesthetized with a field block: 1% lidocaine *without* epinephrine is injected subcutaneously into the skin around the base of the ear. Simple skin wounds may be closed in a single layer. Lacerations to the underlying cartilage should be repaired with absorbable material. If there is significant degloving or loss of overlying tissue, a consultant should be involved; portions of aural cartilage may be saved temporarily in a distant dermal pocket for later reconstruction. Because cartilage is avascular, chondritis, when it occurs, requires extensive débridement and is disfiguring. No randomized trials have been performed, but when the cartilage of the pinna requires repair, antibiotic prophylaxis is recommended. Compressive ear dressings (splints) are indicated after any significant repair. Ear injuries occurring before age 1 year or injuries to both ears in children are rare and should raise the suspicion of abuse.[92]

Eyes

Simple eyelid lacerations may be repaired in a single layer. Wound adhesives should be used with great caution anywhere near the eye; care must be taken not to glue the eyelids open or shut. Lacerations that involve deeper structures, loss of tissue, or the lid margin should be referred to a consultant. The integrity of the lacrimal apparatus can be assessed by instilling fluorescein into the eye and assessing for dye in the wound. A consultant should handle any injury to the sac or lacrimal duct.

Eyebrow lacerations are common because of the overhanging supraorbital ridge. Careful wound exploration should be performed to assess the integrity of the underlying bony structure. No shaving should be performed because the brow hairs may not regrow, and the hairs are necessary for realignment. If débridement is required, it should be done parallel to the hair follicles (skived) rather than perpendicular to the skin. This approach minimizes the bald area of the scar. Closing the deeper muscular layers preserves the normal expressive function of the brow. Injuries to the globe are discussed in Chapter 71.

FRACTURES AND DISLOCATIONS

For the emergency physician, the key to facial fractures is accurate diagnosis and appropriate referral. Many nondisplaced or minimally displaced facial fractures may be handled on an outpatient basis, with definitive repair or fixation delayed several days. In adults, fractures develop firm fibrous union within approximately 10 to 14 days; however, definitive repair is performed most easily before day 7. Methods for diagnosing fractures were discussed previously. Fractures to the face of young children are relatively rare and may be incomplete or greenstick fractures. Fibrous union in these cases is rapid; early reduction (within 3 days) is recommended.

Antibiotics are indicated for open fractures and fractures that violate a sinus. Patients with fractures through the nasoethmoid complex that violate the maxillary bones or the floor of the orbit should be cautioned to avoid sneezing and blowing the nose because these activities force air out into the soft tissues of the face.

Surgical repair of simple nasal fractures may be performed closed and the nose splinted internally or packed. Repair of fractures of the floor of the orbit, when necessary, may require the placement of a silicone patch to occlude the opening into the maxillary sinus. Operative repair of most other fractures of the face is performed with use of small metal plates (microplates), screws, or wires to stabilize fragments by attaching them to unbroken segments of bone. Efforts are made to return the features to their unfractured locations and to regain facial symmetry, if possible. Complex facial fractures may have to be repaired in a staged fashion, depending on the patient's degree of illness and the amount and quality of the bone remaining. Much of this surgery

www.ketabpezeshki.com 66485457-66963820

is best accomplished when the fragments are still freely mobile but initial swelling has been reduced, on postinjury days 3 to 5.

Specific Considerations by Site

Forehead

Fractures through the superior forehead may occur above the level of the frontal sinus. These are actually skull fractures rather than facial fractures and should be addressed with special attention to risk of injury to the underlying brain. Unlike other skull fractures, frontal skull fractures often require repair for cosmesis alone. More often, fractures in this area involve the anterior portion of the frontal sinus. If even minimally displaced, these fractures require elevation for cosmesis. Fractures through the anterior wall of the frontal sinus are likely to continue through the posterior wall, and a CT scan should be performed to look carefully for this complication; if present, a CSF leak should be assumed until proved otherwise. CSF leaks into the frontal sinus may also manifest in a delayed manner, days or years after the initial injury.[93] With many frontal sinus fractures, complex repair or obliteration may be required to treat this complication.[94]

Orbit

The most common simple fracture of the orbit is blow-out fracture of the orbital floor, often caused by a fisted blow or ball striking the globe, increasing intraorbital pressure enough to force orbital contents through the floor. This injury may happen without other significant bony facial injury. When displaced, the bony fragments sag into the underlying maxillary sinus. If the inferior rectus muscle is entrapped in the defect, the patient is unable to elevate the globe on the affected side, resulting in diplopia on upward gaze. Stretch or compression of the infraorbital nerve, which passes through the floor, may cause anesthesia over the anteromedial cheek and upper lip. Because signs of entrapment may result from contusion and edema and be self-limited, immediate repair is not necessary, but careful follow-up is required. Repair typically is performed 1 or 2 weeks after the injury for persistent enophthalmos or diplopia. Because of the acute limitation in the visual field, discharge instructions for patients with acute diplopia should include patching for comfort and a request not to drive until the diplopia is resolved.

Fractures of the medial orbital wall, through the lamina papyracea, are often associated with nasal injury or more general midface fractures, particularly with telescoping of the midfacial skeleton. Herniation of orbital contents into the ethmoids may occur. In one study, patients with orbital fractures with a medial component were more likely to have ocular signs of diplopia or exophthalmos than patients with fractures that did not involve the medial wall.[95] Fractures involving the superior orbit include the base of the frontal sinus, and all of the concerns about the anterior skull mentioned previously apply. Herniation of orbital structures into the frontal sinus is rare but can occur.

Many orbital fractures involve more than one wall of the orbit and may be present in a constellation with complex midface fractures (Fig. 42-11). Several classification schemes aimed at improving communication among emergency physicians, radiologists, and maxillofacial surgeons have been proposed,[96-98] but no classification system is generally accepted.

Injury to the orbit, particularly fractures, can cause a hematoma to form within the orbit, behind the globe. If significant in size, a retro-orbital hematoma can elevate retro-orbital pressure causing acute exophthalmos and a compartment syndrome of the retro-orbital space. Stretch on the retinal artery limiting flow to the retina or neuropraxia of the retinal nerve may cause decreased visual acuity or blindness. Orbital emphysema associated with fractures of the medial wall or floor rarely results in a space-filling lesion with the same effect. This is a true emergency; drainage of the air or blood via lateral canthotomy with cantholysis is indicated to save the patient's vision. Needle aspiration of entrapped air may also be attempted, but this may be best left to a consultant, given the proximity of the globe.

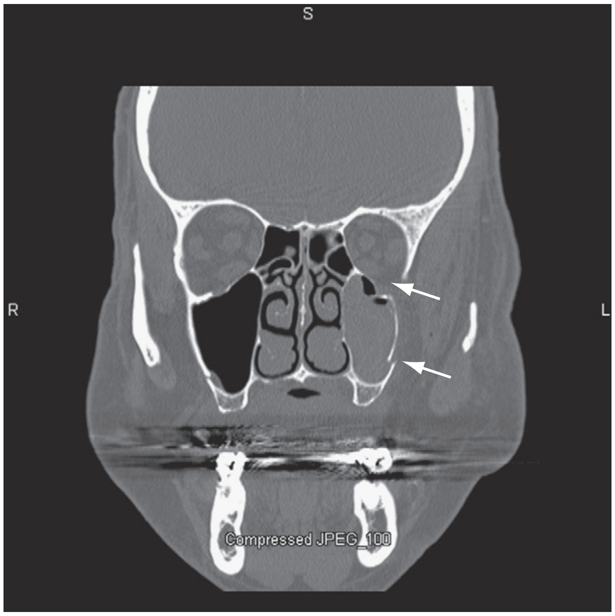

Figure 42-11. Computed tomography shows fractures of the left orbital floor (*top arrow*) and left lateral maxillary wall (*bottom arrow*). There is streak artifact from dental devices.

Midface

Tripod (or trimalar) fractures are among the simplest fractures of the midface and include fractures of three bones: the lateral orbit, the zygoma, and the maxilla (see Fig. 42-10). Typically caused by a direct blow, these fractures are often displaced and require operative stabilization. If left untreated, the area may "sink" posteriorly and inferiorly, giving an unacceptable appearance of facial asymmetry emphasized by the inferior position of the orbit and malar flattening. On the initial physical examination, there may be a large contusion over the cheekbone, enophthalmos, or malocclusion of the upper teeth. Fractures through the anterior wall of the maxillary sinus may denervate the maxillary teeth because the dentoalveolar nerves run in tunnels in this area.

More complex fractures of the midface are classified with the Le Fort system, although many complex fractures defy classification with this system. A Le Fort I fracture involves a transverse fracture through the maxilla above the roots of the teeth and may be unilateral or bilateral. Patients may report malocclusion, and the maxilla may be mobile when the upper teeth are grasped and rocked. A Le Fort II fracture is typically bilateral and pyramidal in shape. It extends superiorly in the midface to include the fracture of the nasal bridge, maxilla, lacrimal bones, orbital floor, and rim. In these cases the nasal complex moves as a unit with the maxilla when the teeth are grasped and rocked. In the current age of CT scans, in which the full extent of comminution can be appreciated, simple Le Fort III fractures are rare but essentially involve fracturing of the connections between the elements of the skull and the face (craniofacial dysjunction). These fractures start at the bridge of the nose; extend posteriorly along the medial wall of the orbit (ethmoids), along the floor of the orbit (maxilla), and through the lateral orbital wall; and finally break through the zygomatic arch.

www.ketabpezeshki.com 66485457-66963820

Intranasally, they extend through all the lesser bones to the base of the sphenoid and frequently are associated with a CSF leak.

Significant force to the bridge of the nose may fracture the deep nasoethmoid complex without creating a formal Le Fort pattern. CT is the initial test of choice in this setting. Fractures to the central portion of the ethmoid bone (cribriform plate) are likely to be associated with a CSF leak and commonly result in anosmia.

If possible, patients with a CSF leak should have the head elevated 40 to 60 degrees. Head elevation minimizes the intracranial pressure, with the idea of decreasing the flow and allowing the leak to seal. Often these patients are treated with antibiotics; however, this practice is controversial, and most of the studies supporting it involve small, local case series.[93] In one meta-analysis, antibiotics did not decrease the rate of meningitis in the setting of CSF leak.[100] Neurosurgeons should be involved in the care of patients with CSF leaks, although many leaks will spontaneously resolve.[101]

Fractures involving the deeper structures of the midface may be associated with significant bleeding into the nose or oropharynx. Anterior nasal packing may be performed safely in the adult patient with multiple trauma. Even a 10-cm anterior pack should not reach the skull base in a skeletally mature person. Significant or massive bleeding into the posterior nasopharynx presents a complex problem and occurs in less than 1% of patients with midface fractures. It may be treated with nasal packing and immediate fracture reduction.[47,69] Unless the anatomy is well understood and the skull base known to be intact, the use of a long balloon catheter (Foley) should be avoided for control of posterior bleeding. The unintended positioning of these items within the intracranial[103,104] or intraspinal space[105] during blind nasal insertion has been well documented, and when the face is grossly distorted, preinsertion measurement or other methods of preventing this outcome have not been adequately tested. There are no reports of the intracranial placement of commercial catheters designed for posterior epistaxis, but if the midface is significantly distorted or telescoped, they may be long enough to reach the intracranial space. An alternative method for containing posterior nasal bleeding is to provide compression by packing the area with gauze by hand from the oropharynx after intubation.

Zygoma

Isolated fractures of the zygoma are relatively rare, usually the result of a direct blow, and are often displaced. Because the condyle of the mandible may disturb zygomatic fragments while moving, fractures with significant displacement are likely to result in trismus or discomfort with mouth opening. Surgical repair is usually required to return the cheekbone to an acceptable position.

Mandible

Fractures of the mandible can result from any significant force applied to its U shape. Because of its shape, multiple fractures may result from a single blow, and the fracture sites may be distant from the site of impact. Depending on the location of the fractures, the patient may have trismus (fractures of the coronoid process, neck, or rami), dental malocclusion, swelling, and tenderness intraorally or externally. Anesthesia of the lower lip may occur if there is damage to the inferior dental nerve.

Fractures of the symphysis, body, angle, or rami usually require early splinting, typically by the placement of arch bars to accomplish interdental fixation, commonly known as “wiring the jaw shut.” Fixation limits fracture motion, decreases the patient’s discomfort, and, if the fracture is minimally displaced, may provide complete fracture care. Impacted and nondisplaced fractures occasionally are treated with only a soft diet, and fractures of the coronoid alone usually require no intervention, but these decisions should be made in consultation with an oral surgeon or other specialist. Arch bars may be placed in the ED or operating room and typically are placed by a specialist (see Fig. 42-6). Fracture reduction may require the extraction of teeth adjacent to the fracture line. Patients with open fractures require antibiotics and usually hospitalization. When the fractures are closed and adequate stabilization can be obtained, elective operative repair can be performed as an outpatient procedure in 3 to 5 days.

In one study, 17 to 22% of pediatric patients 4 to 11 years old developed facial growth disturbances after a fractured mandible and required later orthognathic surgery for correction. Children younger than 4 or older than 11 years were much less likely to develop this complication.[106,107] Because of the frequency of this complication, children in this age group who have sustained a blow to the chin and who have any trismus or tenderness over the TMJ should be assessed carefully with panorex imaging for condylar fracture and referred appropriately.

Dental and Alveolar Trauma

Trauma to the teeth may occur with or without other facial injury. In the setting of caries, tooth fractures may occur with eating relatively soft foods. Tooth fractures are classified by the Ellis system. Class I fractures involve only the enamel of the tooth, are not painful, and can await dental evaluation on an outpatient basis. Class II fractures expose the yellow dentin and may be painful. These also can await dental care, but they may be covered with a dressing of calcium hydroxide and aluminum foil. Class III fractures expose the dental pulp, seen as a red line or dot, and are exquisitely painful. These require early evaluation by dentists or endodontists.

Sufficient energy to the area avulses teeth from their sockets. Multitrauma patients, particularly patients who are intoxicated, required to be supine for cervical spine immobilization, or neurologically impaired, should have avulsed or mostly avulsed teeth removed from the mouth and placed externally in saline as an aspiration precaution. In a critically ill multitrauma patient, avulsed teeth should be among the lowest priorities and are reimplanted only if the care of other injuries allows it and there is no risk of aspiration if the teeth loosen.

To perform a reimplantation, the physician disturbs the socket as little as possible, gently rinses off the tooth (the root should not be wiped), and places it into the socket where it “clicks” into place. If the tooth is only partially avulsed, extruded, or laterally luxated, it should not be removed; it should be reimplanted or relocated. Intruded teeth should not be manipulated. Reimplantation can be painful and may require local anesthesia with a regional dental block. Alternatively, the area of a single socket may be anesthetized by placing approximately 0.5 mL of 1% lidocaine without epinephrine into the buccal sulcus and gum on the outer side of the alveolar ridge. After reimplantation, the tooth requires stabilization with acrylic splint or wiring to the adjacent teeth.

Reimplanted teeth may or may not “take” acutely, but it can take weeks to assess the final success of reimplantation. The length of time out of the socket and storage process seem to play a critical role in the initial success.[108] Among teeth successfully reimplanted in less than 1 hour, more than 66% have been found to be radiographically healed and functionally normal after 5 years. For teeth successfully reimplanted after 3 hours, more than 80% have been found to have signs of inflammation and bone resorption after the same period of time.[109,109a]

In children, the front maxillary incisors are most commonly avulsed. After reimplantation, these teeth may ankylose and fail to “grow out” normally, requiring later extraction or orthodontic intervention for cosmesis. This situation is most common in children age 6 to 10 years with avulsed adult teeth.[110]

www.ketabpezeshki.com 66485457-66963820

Avulsed teeth missing after significant trauma should be carefully sought, including via a chest x-ray examination. In an acute event, the patient may not recall aspirating a tooth; this is more likely if the patient is intoxicated or neurologically impaired. If the tooth is below the diaphragm on the film, it does not require retrieval. Teeth lodged in a bronchus or the esophagus require bronchoscopic or endoscopic retrieval. Aspirated teeth result in pulmonary abscess formation unless removed.

Fractures through the alveolar ridge may result in a group of teeth being dislodged and out of position, often leaning inward. These teeth require stabilization with wire or acrylic splinting after fracture reduction has returned the teeth to their correct location. The involved teeth may or may not survive after such a fracture, and careful follow-up with a dentist or oral surgeon is required.

Temporomandibular Joint

The TMJ is complex, with the condyle of the mandible undergoing rotation and translation anteriorly during normal mouth opening. The function of the joint is preserved by a meniscus, which overlies the condyle. Essentially, the joint between the meniscus and the condyle is a hinged joint, allowing rotation, and the joint between the meniscus and the temporal bone is a sliding joint, allowing translation. A formal, thick joint capsule does not exist at the anteromedial portion of the joint; loose, relatively weak synovial tissue is positioned here to allow translation to occur.

Trauma to the TMJ may tear the meniscus or injure the collateral ligaments holding it in a normal position. This injury can cause the meniscus to fail to translate normally, resulting in clicking or popping as it catches up to the condyle or inability to open the mouth fully because the meniscus completely fails to translate. Patients without fracture but with acute pain and difficulty with mouth opening should be placed on soft foods, asked not to yawn or struggle to open their mouths widely, and referred to an oral surgeon with expertise in TMJ pathology. Pediatric patients with post-traumatic internal derangements of the TMJ are prone to asymmetry of facial growth and retrognathia. In one study, 88% of children injured before their ninth birthday had significant facial abnormalities years later.[111]

Because of the anatomy and function of the joint, anterior dislocation of the TMJ can occur after widely yawning, laughing, kissing, singing, or other activities that involve spontaneous, wide opening of the mouth. When the condyle is out, spasm of the muscles of mastication prevents spontaneous reduction. Significant trauma is more likely to cause a fracture-dislocation. Simple dislocation may be unilateral or bilateral, and the patient reports being unable to close the mouth. In unilateral dislocation, the jaw is rotated laterally away from the affected joint; bilateral dislocation causes significant protrusion of the jaw. The jaws of these patients are often so widely open that they cannot swallow their secretions and are actively drooling. Speech is often garbled by the patient's inability to touch the tongue to the roof of the mouth or the maxillary teeth. There is a depression in the area of the affected TMJ on inspection of the patient's face.

If the mechanism of injury suggests a fracture, the area should be imaged with plain x-ray or panorex examination before reduction is attempted. For reduction of a simple dislocation, the patient should be seated upright. For leverage to be maximized, the best position may be for the patient to be seated in a regular chair with the operator standing in front of the patient. As in dislocations of other joints, adequate analgesia and sedation are required for success. With the thumb or index finger placed into the buccal sulcus on either side of the mouth, the angle of the jaw is pressed downward while the symphysis is rotated (chin) upward and backward. Care should be taken not to place fingers along the crowns of the teeth; when relocation occurs, spasm of the muscles of mastication snaps the mouth shut with force. If this is the only location possible for the physician's fingers, gauze wrappings should be placed to protect them.

Panorex or x-ray films are suggested after the first episode of dislocation. The patient is discharged with pain medicine, a soft diet for 2 weeks, and outpatient follow-up with an oral surgeon. Patients with an episode of dislocation are predisposed to a recurrence. In patients who experience frequent dislocation, interdental fixation may be required for 2 or 3 weeks.

DISPOSITION

The decision to discharge or admit patients with facial trauma depends on their associated injuries, general injury severity, and plans for treatment. Patients with isolated facial trauma that has been repaired or stabilized and with no airway issues are usually discharged.

KEY CONCEPTS

- The face is central to the patient's ability to breathe, eat, and communicate. Injuries to the face can have serious psychological and psychosocial consequences.
- Facial injuries may be prevented by the appropriate use of safety belts, child restraints, air bags, helmets, and mouth and face guards.
- The epidemiology of facial injury is changing, with an increasing proportion of injuries occurring as a result of interpersonal violence. A careful history is required, and the possibility of abuse should be considered for every patient.
- Shock from facial trauma is rare and results only from obvious external bleeding. Facial injuries should not distract the emergency physician from aggressively searching for other causes of shock.
- Assertive management of the airway is indicated in a patient with significant facial injuries. Surgical management (cricothyroidotomy) may be required, particularly with gunshot wounds.
- Directed facial CT scanning is the best imaging technique in patients with obvious injuries.
- Definitive treatment may be delayed if necessary to allow other serious injuries to be addressed.

Chapter 43

Spinal Injuries

Amy H. Kaji, Edward J. Newton, and Robert S. Hockberger

PERSPECTIVE

Background

Prehistoric humans undoubtedly suffered little in the way of significant spinal injury. Their semierect posture combined with well-developed posterior cervical muscles protected the cervical spine against day-to-day trauma. Evolution, however, did much to undo this initial protective state. As humans assumed an upright posture, the shoulders dropped away from the newly elevated head, and the hypertrophied paraspinous muscles atrophied. This increased the head's range of motion but diminished the spine's protection. Although civilization heightened man's inventiveness, it unfortunately did little to curb his aggressiveness. Automobiles replaced horse-drawn carriages, and fists and clubs gave way to knives and guns, making spinal injuries more common in the modern era.

Epidemiology

Statistics from the National Spinal Cord Injury Database show that motor vehicle collisions (MVCs) account for roughly 40% of all spinal injuries.[1] Speeding, alcohol intoxication, and failure to use restraints are major risk factors. The next most common cause of spinal cord injury (SCI) is falls, followed by acts of violence (primarily gunshot wounds) and sporting activities. There are currently more than 260,000 spinal injury victims living in the United States, and 12,000 new cases occur each year. Approximately 80% of victims are male, and the average age at injury is 40 years. The lifetime cost to care for SCI victims ranges from $500,000 for people older than 50 years with incomplete motor function to over $3 million for people younger than 25 years with complete paraplegia. The total cost to society from lifelong medical expenses and lost productivity for all age groups and types of spinal injuries is estimated to be more than $5 billion.[2] The devastating emotional and psychological impact on the victims and their families is incalculable.

PRINCIPLES OF DISEASE

Anatomy and Physiology

The human spine consists of 33 bony vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into one), and 4 coccygeal (usually fused into one) (Fig. 43-1).[3] These 26 individual units are separated from one another by flexible intervertebral disks and connected to form a single functioning unit by a complex network of ligaments. In addition to providing basic structural support, the vertebral column protects the spinal cord, which extends from the midbrain to the level of the second lumbar vertebra. Nerves that receive and transmit sensory, motor, and autonomic impulses pass to and from the spinal cord through intervertebral foramina.

Spinal injuries involve fractures in 85% of cases. Ten percent are purely ligamentous injuries, and 5% are SCI without radiographic abnormality (SCIWORA) in which the spinal cord is injured directly without any radiographic evidence of bony or ligamentous injury.[4] *Stability* of a spinal injury refers to the resistance to displacement of fracture fragments or, in the case of ligamentous injury, the entire vertebral unit. Displacement may occur at the time of injury or progressively over hours to weeks and can cause or worsen damage to the spinal cord or nerve roots. There are several conceptual models for assessing the stability of subaxial spinal column injuries, but the most commonly used one is the three parallel vertical column model proposed by Denis (Fig. 43-2)[5] The anterior column is formed by alternating vertebral bodies and intervertebral disks surrounded by the annulus fibrosus capsule and the anterior longitudinal ligament. The middle column consists of the posterior part of the annulus fibrosus and posterior vertebral wall, the posterior longitudinal ligament, the spinal cord, the paired laminae and pedicles, the articulating facets, the transverse processes, and the nerve roots and vertebral arteries and veins. The posterior column consists of the spinous processes, nuchal ligament, interspinous and supraspinous ligaments, and ligamentum flavum. Disruption of only a single column usually preserves a high degree of stability but does not preclude SCI from displaced fracture fragments. Disruption of two columns results in an injury that is stable in one direction but unstable in another (e.g., stable in flexion but unstable in extension). Disruption of all three columns produces a highly unstable injury. Until the full extent of the injury is clear, all spinal injuries should be treated as potentially unstable, and spinal immobilization should be maintained.

Pathophysiology

Classification of Spinal Column Injuries

Acute spinal injuries are classified according to the mechanism of trauma: flexion, flexion-rotation, extension, and vertical compression (Table 43-1).[6,7]

Flexion. Pure flexion injuries involving the C1-C2 complex can cause unstable *atlanto-occipital* or *atlantoaxial joint dislocation,* with or without an associated fracture of the odontoid (Fig. 43-3). These injuries are considered unstable because of their location and the relative lack of muscle and ligamentous support.

In pure flexion injuries below C2, a longitudinal pull is exerted on the strong nuchal ligament complex, which usually remains intact. Most of the force is expended on the vertebral body

Table 43-1 Classification of Spinal Injuries

MECHANISM OF SPINAL INJURY	STABILITY
Flexion	
Wedge fracture	Stable
Flexion teardrop fracture	Extremely unstable
Clay shoveler's fracture	Stable
Subluxation	Potentially unstable
Bilateral facet dislocation	Always unstable
Atlanto-occipital dislocation	Unstable
Anterior atlantoaxial dislocation with or without fracture	Unstable
Odontoid fracture with lateral displacement fracture	Unstable
Fracture of transverse process	Stable
Flexion-Rotation	
Unilateral facet dislocation	Stable
Rotary atlantoaxial dislocation	Unstable
Extension	
Posterior neural arch fracture (C1)	Unstable
Hangman's fracture (C2)	Unstable
Extension teardrop fracture	Usually stable in flexion; unstable in extension
Posterior atlantoaxial dislocation with or without fracture	Unstable
Vertical Compression	
Bursting fracture of vertebral body	Stable
Jefferson fracture (C1)	Extremely unstable
Isolated fractures of articular pillar and vertebral body	Stable

anteriorly, causing a *simple wedge fracture.* Radiographically, there is a diminished height and increased concavity of the anterior border of the vertebral body, an increased density of the vertebral body resulting from bony impaction, and prevertebral soft tissue swelling (Fig. 43-4). Because the posterior column remains intact, this injury is usually stable and rarely accompanied by nervous system damage. However, spinal instability may occur with severe wedge fractures (loss of more than half the vertebral height) or multiple adjacent wedge fractures, and such injuries are best treated as being potentially unstable.

A *flexion teardrop fracture* results when severe flexion forces cause anterior displacement of a wedge-shaped fragment (resembling a teardrop) of the anteroinferior portion of the involved vertebral body (Fig. 43-5). Because this injury commonly involves anterior and posterior ligamentous disruption, it is often associated with neurologic injury and is highly unstable.

The *clay shoveler's fracture* is an oblique fracture of the base of the spinous process of one of the lower cervical segments (Fig. 43-6). The injury derives its name from its common occurrence in clay miners in Australia during the 1930s. When a miner lifted a heavy shovelful of clay, abrupt head flexion against the supraspinous ligament resulted in an avulsion fracture of the spinous process. Today, this fracture is more commonly seen after direct trauma to the spinous process and after sudden deceleration MVCs that result in forced neck flexion. Because this injury involves only the spinous process, it is stable and not associated with neurologic involvement.

Pure *spinal subluxation* occurs when the ligamentous complexes rupture without an associated bony injury. This injury begins posteriorly in the nuchal ligament and proceeds anteriorly to involve other ligaments. The lateral radiograph with the neck in the neutral position may show a widening of both interspinous and intervertebral spaces posteriorly at the level of injury, and oblique views may demonstrate a widening or abnormal alignment of the facets (Fig. 43-7). These findings are often subtle and may be missed if flexion and extension views are not obtained. Although rarely associated with neurologic damage, this injury is potentially unstable.

Bilateral facet dislocations occur when a greater force of flexion causes soft tissue disruption to continue anteriorly to the annulus fibrosis of the intervertebral disk and the anterior longitudinal ligament, resulting in an extremely unstable condition. The forward movement of the spine causes the inferior articulating facets of the upper vertebra to pass upward and over the superior facets of the lower vertebra, resulting in anterior displacement of the spine above the level of injury. Radiographically, the anterior displacement will appear to be greater than one half of the anteroposterior (AP) diameter of the lower vertebral body with the superior facets anterior to the inferior facets (Fig. 43-8).

Shear Injury. Trauma to the head directed in an AP direction may result in fracture of the odontoid process above the transverse ligaments (type I) or, more commonly, at the base of the odontoid process where it attaches to C2 (type II) (Fig. 43-9). Slight angulation of the force may result in extension of the fracture into the body of C2 (type III). Type I odontoid fractures are usually stable because they are an avulsion injury to the odontoid tip. However, if traction forces injure the apical and alar ligaments, then the fracture may become unstable. Type II odontoid fractures are unstable and often complicated by nonunion. SCI is uncommon but can occur. Type III odontoid fractures are also mechanically unstable as they can extend laterally into the superior articular facet of the atlas.

Flexion-Rotation. *Rotary atlantoaxial dislocation* is an unstable injury visualized best on open-mouth odontoid radiographs (Fig. 43-10). If the skull is shown obliquely, there may be a false-positive asymmetry between the odontoid process and the lateral masses of C1. However, when the x-ray film reveals symmetrical basilar skull structures, a unilaterally magnified lateral mass confirms a C1-C2 dislocation.

A *unilateral facet dislocation* involves both flexion and rotation. The rotational component of this injury occurs around one of the facet joints, which acts as a fulcrum. Simultaneous flexion and rotation cause the contralateral facet joint to dislocate, with the superior facet riding forward and over the tip of the inferior facet and coming to rest within the intervertebral foramen. In this position, the dislocated articular mass is mechanically locked in place, making this a stable injury, although the posterior ligament complex is disrupted. The frontal radiograph shows the spinous processes above the level of dislocation displaced from the midline in the direction of the rotation (Fig. 43-11A and B). The lateral radiograph shows a forward displacement of the dislocated segment on the vertebra below (less than one half the AP diameter of this vertebral body) and a rotation of the dislocated vertebra and those above it (Fig. 43-11C and D).

Any cervical fracture or dislocation may cause torticollis, but torticollis may also be caused by a benign process such as a muscle spasm. It may be difficult to differentiate torticollis caused by cervical fracture or dislocation from torticollis caused by severe muscle spasm, however, and oblique projections may be necessary to demonstrate the dislocated facet joint (Fig. 43-11E and F).

Owing to the varying shapes of the articular processes, particularly between the cervical and lumbar regions, different types of flexion-rotation injuries result. In the cervical region, where

articular processes are small, flat, and almost horizontal, unilateral facet dislocations occur as described previously. In the lumbar region, however, where articular processes are large, curved, and nearly vertical, unilateral facet dislocation is rare. Instead, one or both articular processes fracture, and the upper vertebra swings forward. Commonly seen in the thoracolumbar and lumbar region, this rotation fracture-dislocation is unstable (Fig. 43-12).

Extension. The *posterior neural arch fracture* of the atlas (C1) results from the compression of the posterior elements between the occiput and the spinous process of the axis (C2) during forced neck extension (Fig. 43-13). Although the anterior arch and the transverse ligament remain intact, this fracture is potentially unstable because of its location.

The *hangman's fracture,* or traumatic spondylolysis of C2, occurs when the cervicocranium (the skull, atlas, and axis functioning as a unit) is thrown into extreme hyperextension as a result of abrupt deceleration. Bilateral fractures of the pedicles of the axis occur with or without dislocation (Fig. 43-14). Although this lesion is unstable, cord damage is often minimal because the AP diameter of the neural canal is greatest at the C2 level, and the bilateral pedicular fractures permit the spinal canal to decompress itself. Originally described in victims of hanging injury, today it is most often the result of head-on MVCs.

The *extension teardrop fracture* occurs when abrupt extension of the neck causes the anterior longitudinal ligament to pull the anteroinferior corner of a vertebral body away from the remainder of the vertebra, producing a triangular fracture that is radiographically similar to the flexion teardrop fracture. Often occurring in lower cervical vertebrae (C5-C7) from diving accidents, this injury may be associated with a central cord syndrome, which is discussed later, and is caused by the ligamentum flavum buckling into the spinal cord.[8] Because the posterior elements remain intact, this injury is stable in flexion but potentially unstable in extension.

Vertical Compression. Vertical compression injuries occur in the cervical and lumbar regions, which are capable of straightening at the time of impact. When forces are applied from either above (skull) or below (pelvis or feet), one or more vertebral body endplates may fracture. The nucleus pulposus of the intervertebral disk is forced into the vertebral body, which is shattered outward, resulting in a *burst fracture* (Fig. 43-15). The lateral radiograph shows a comminuted vertebral body, and there will typically be greater than 40% compression of the anterior vertebral body,

www.ketabpezeshki.com 66485457-66963820

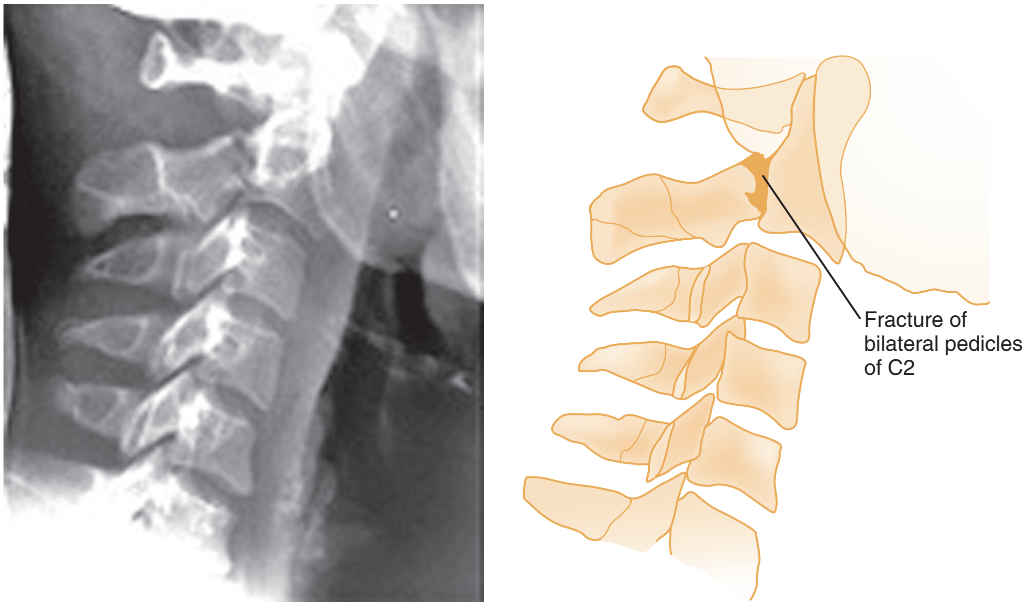

Figure 43-14. Hangman's fracture. Mechanism: extension. Stability: unstable. Fracture lines extending through the pedicles of C2 are well visualized. Retropharyngeal soft tissue swelling is apparent.

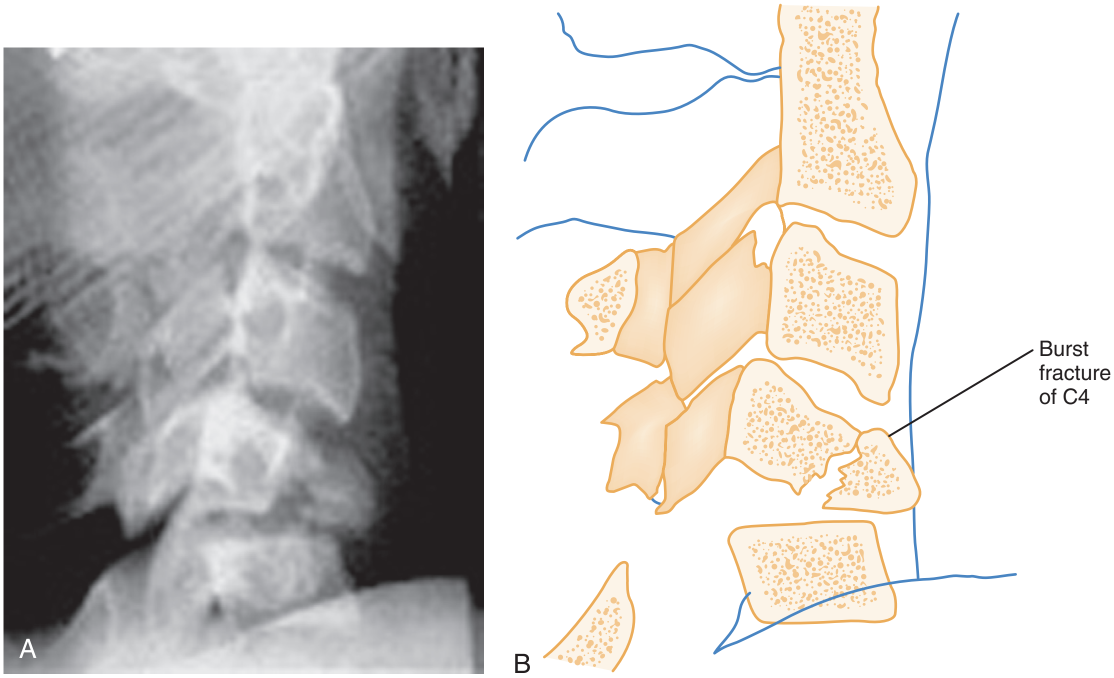

Figure 43-15. Burst fracture of a vertebral body. Mechanism: vertical compression and flexion. Stability: unstable. **A** and **B,** There is a compression fracture of the C4 vertebral body. During the bursting process, the anterior segment of the fracture protrudes anteriorly, and its posterior aspect protrudes posteriorly into the spinal canal. Such protrusion is often associated with anterior cord syndrome. The cervical spine is abnormally angulated.

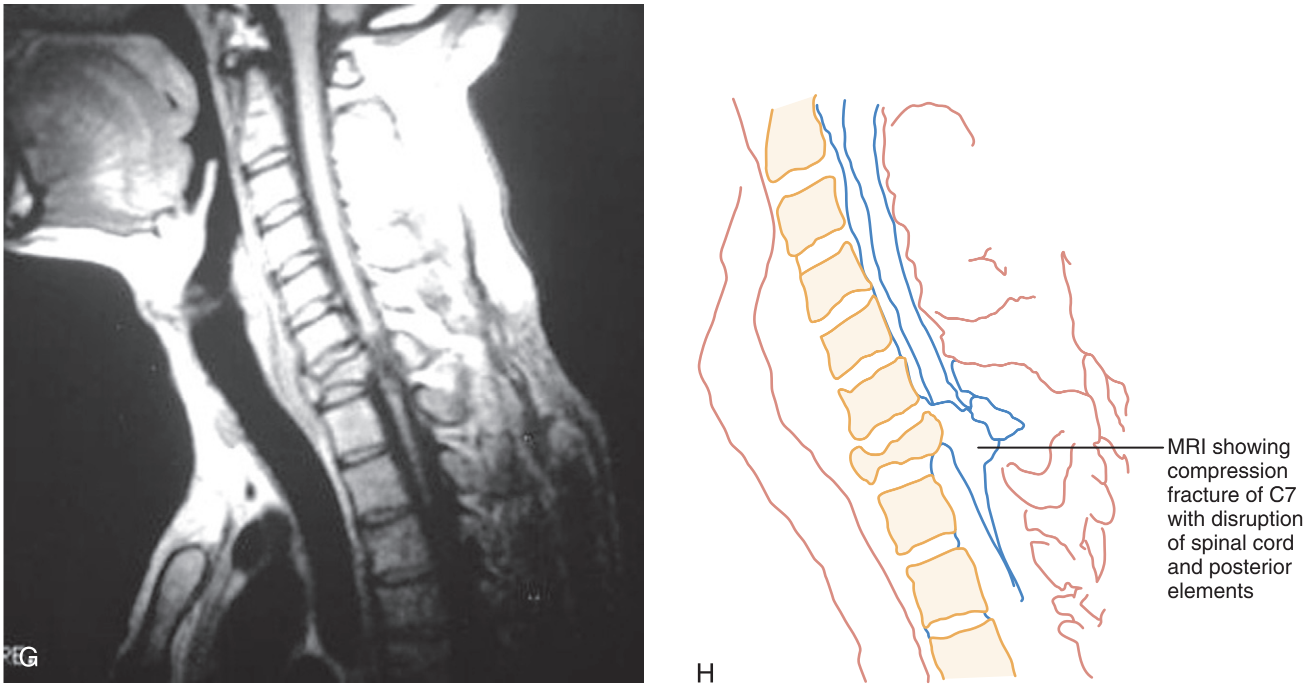

Figure 43-15, cont'd. G and H, Magnetic resonance image showing a burst fracture of C7 with complete spinal cord disruption.

which helps differentiate it from the simple wedge fracture. The frontal radiograph demonstrates a characteristic vertical fracture of the vertebral body, which will also help differentiate it from the simple wedge fracture and the flexion teardrop fracture. This is a stable fracture because all the ligaments remain intact. However, fracture fragments may impinge on or penetrate the ventral surface of the spinal cord and cause an anterior cord syndrome (see Fig. 43-15).

The *Jefferson fracture* of C1 is an extremely unstable injury that occurs when a vertical compression force is transmitted through the occipital condyles to the superior articular surfaces of the lateral masses of the atlas. This force drives the lateral masses outward, resulting in fractures of the anterior and posterior arches of the atlas and a disruption of the transverse ligament. Because this injury is often associated with prevertebral hemorrhage and retropharyngeal swelling, the lateral film may demonstrate a widening of the predental space between the anterior arch of C1 and the odontoid, or dens. The open-mouth view will demonstrate a bilateral offset of both right and left lateral masses of C1 relative to the lateral masses of C2. A fracture should be diagnosed when the sum of the offset distances from the right and left sides exceeds 7 mm (Fig. 43-16). However, when the fragments are minimally displaced, the Jefferson fracture is difficult to recognize, and computed tomography (CT) may be necessary.

Vertical compression fractures may rarely result in isolated fractures of the articular pillar or the vertebral body, exhibiting vertical and oblique lines of fracture.

Classification of Spinal Cord Injuries

Primary Spinal Cord Injury. The spinal cord may be injured in a number of ways.[8] First, penetrating trauma or massive blunt trauma with disruption of the vertebral column may cause the transection of neural elements. Because neurons within the central nervous system do not regenerate, such injuries are irreversible. Less severe blunt trauma may have similar effects resulting from a displaced bony fragment or a herniated disk.

Second, when elderly patients with cervical osteoarthritis and spondylosis are subjected to forcible cervical spine extension, the spinal cord may be compressed between an arthritically enlarged anterior vertebral ridge and a posteriorly located hypertrophic ligamentum flavum (Fig. 43-17). This injury frequently results in a central cord syndrome.

Primary vascular damage to the spinal cord, a third mechanism of injury, may occur in several ways. The spinal cord may be compressed by an extradural hematoma, particularly in patients who are on anticoagulants or have bleeding disorders. Vascular injuries should also be suspected when there is a discrepancy between the clinically apparent neurologic deficit and the known level of spinal injury. For example, a lower cervical dislocation may compress the vertebral arteries as they travel within the spinal foramina of the vertebrae. This compression may result in thrombosis and decreased blood flow through the anterior spinal artery that originates from both vertebral arteries at the level of C1 (Fig. 43-18). On physical examination, such an injury may erroneously appear to be localized to the level of C1 or C2. Also, the great radicular artery of Adamkiewicz, originating from the aorta and entering the spinal canal at the level of L1, sends branches as cephalad as T4. Therefore a lumbar fracture or dislocation can produce a neurologic deficit as high as T4.

Secondary Spinal Cord Injury. The maximum neurologic deficit after blunt spinal cord trauma is often not seen immediately and may instead progress over many hours. The histopathology of the so-called "secondary SCI" has been studied extensively in experimental animal models.[9-11] It is now thought that primary SCI initiates a complex cascade of biochemical events that result in progressive ischemia of gray and white matter during the postinjury period (Fig. 43-19). Other factors, such as hypoxia, hypotension, hyperthermia, hypoglycemia, and mishandling by medical personnel, also affect the ultimate extent of SCI.

CLINICAL FEATURES

Neurologic Evaluation

The initial neurologic evaluation of a patient with a suspected spinal injury should begin with simple observation. Careful inspection, beginning with the head and proceeding downward,

www.ketabpezeshki.com 66485457-66963820

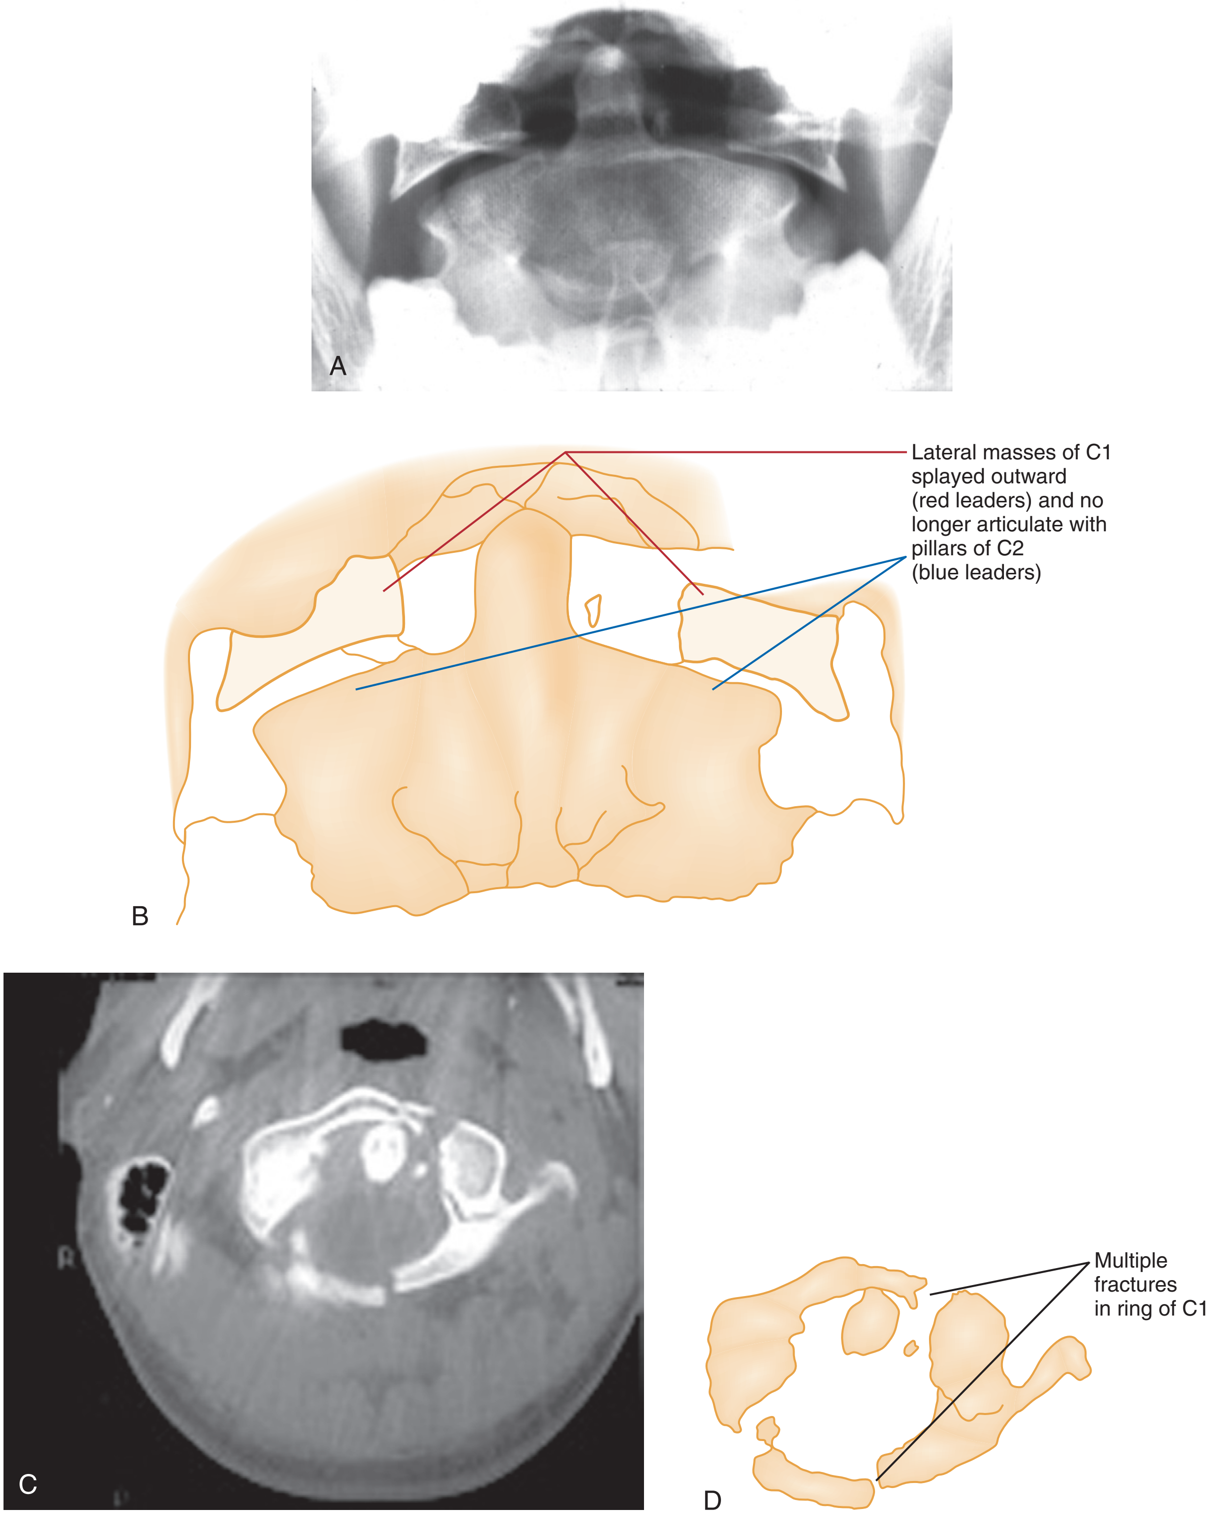

Figure 43-16. Jefferson fracture. Mechanism: vertical compression. Figure 43-18. Mechanism of vascular injury of the spinal cord resulting from cervical vertebral injury.

may reveal signs of possible spinal involvement. Significant head and facial trauma have a 5 to 10% incidence of associated cervical spine injuries.[12,13] Scapular contusions suggest a rotation or flexion-rotation injury of the thoracic spine. Chest and neck abrasions from automobile shoulder belts and lower abdominal markings from lap belts indicate possible blunt carotid and vertebral injuries, as well as spinal, intrathoracic, and intra-abdominal injuries. As occurs with falls from considerable heights, injuries to the gluteal region, calcaneal fractures, and severe ankle fractures suggest a compression type of spinal injury.

The patient should be observed for the presence and symmetry of both voluntary and involuntary movements. Because the diaphragm is innervated by the phrenic nerve, which originates at C3-C4, an abnormal, abdominal breathing pattern may provide an important clue to a cervical injury. The presence of Horner's syndrome, characterized by unilateral ptosis, miosis, and anhidrosis, may result from disruption of the cervical sympathetic chain, usually between C7 and T2.[5] Priapism may occur with severe SCI, and it is often associated with spinal shock, which is a transient reflex depression of the spinal cord below the level of the injury.

The physician should speak with the patient during the inspection process. This important part of the patient's assessment should not be overlooked, because it provides the patient with reassurance and the physician with valuable information. Patients may experience pain in the sensory dermatome corresponding to the injured spinal level. For example, a C2 lesion may cause occipital pain, whereas discomfort in the trapezius muscle, particularly in the absence of signs of local trauma, suggests a C5 injury. Past medical history is important because certain conditions predispose patients to cervical injury. Patients with Down syndrome are

www.ketabpezeshki.com 66485457-66963820

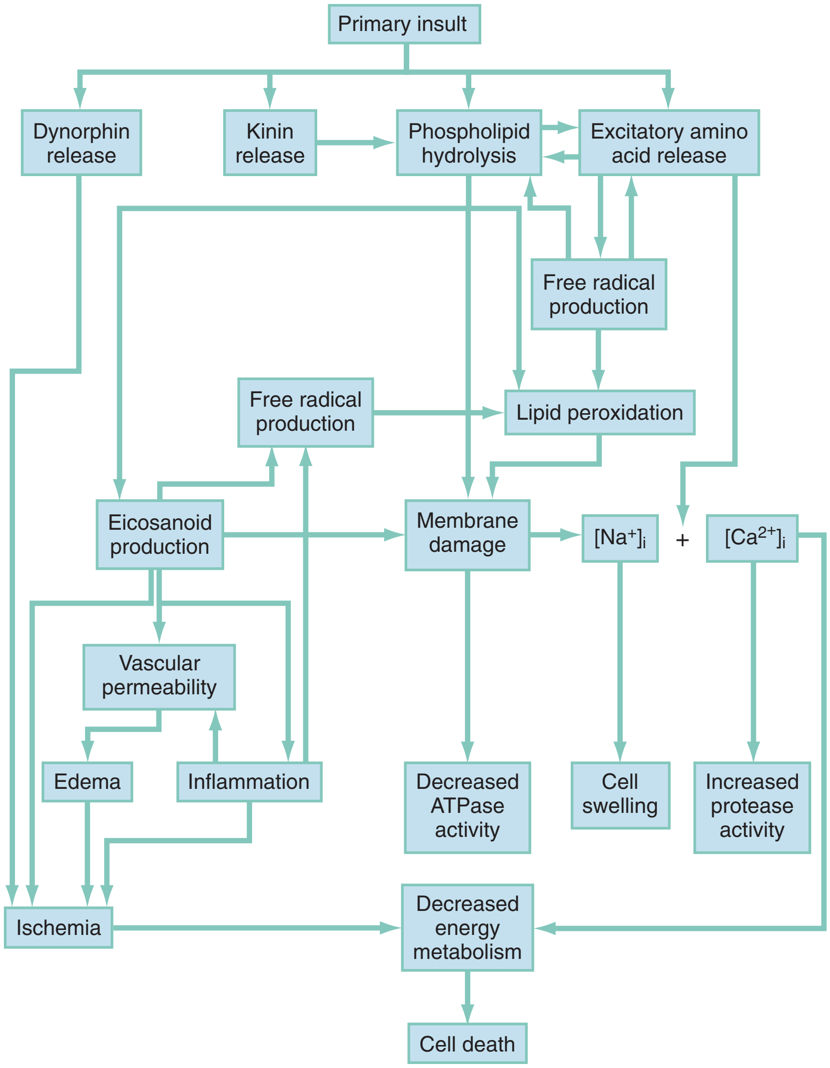

Figure 43-19. Speculative paradigm of secondary pathophysiologic events after primary traumatic injury to the spinal cord. *Ca*$^{2+}$, calcium ion; *Na*$^{+}$, sodium ion. (From Anderson D, Hall E: Pathophysiology of spinal cord trauma. Ann Emerg Med 22:989, 1993.)

predisposed to atlanto-occipital dislocation, whereas rheumatoid arthritis patients are prone to rupture of the transverse ligament of C2.

Palpation of the entire spine and paraspinal musculature may reveal areas of tenderness, deformity, or muscle spasm. A "gibbus" deformity or step-off may be appreciated with severe subluxation. Widening of an interspinous space indicates a tear in the posterior ligament complex and a potentially unstable spinal injury.

The motor activity of the body is complex. Because a single motion is often governed by muscles innervated by multiple spinal segments, localizing a spinal lesion based solely on an assessment of motor function is extremely difficult. Testing the presence and strength of those motions outlined in Table 43-2, however, provides a rapid baseline assessment. When a deficit is noted, the motor and neurologic examination should be repeated at frequent intervals because progression of dysfunction may occur. If there is apparent total loss of function, every effort should be made to elicit the most minimal of motor responses because any response markedly improves the prognosis. A slight toe flicker in an otherwise paralyzed individual indicates that the patient may again eventually walk unassisted.

The presence of cord-mediated *deep tendon reflexes* can be helpful as a localizing, diagnostic aid (Table 43-3). Classically,

muscle paralysis associated with intact deep tendon reflexes indicates an upper motor neuron (spinal cord) lesion, whereas paralysis associated with absent deep tendon reflexes indicates a lower motor neuron (nerve root or cauda equina) lesion. This differentiation is important because the latter condition is often caused by a surgically correctable lesion. After the initial period of areflexia, reflexes gradually return after 1 to 3 days, and after 1 to 4 weeks, patients with SCI will manifest characteristic hyper-reflexia and spasticity.[14] Because reflexes are typically absent during the initial phase of spinal shock, the examination of reflexes is less useful in the emergency department.

Sensory function can be quickly evaluated through use of a structured approach (Table 43-4) or a graphic sensory dermatome chart (Fig. 43-20). After locating an area of hypesthesia, one should move the sensory stimulus from areas of decreased sensation outward, rather than the reverse, because patients are more sensitive to the appearance of sensation than to its disappearance. This test should be performed first with a cotton wisp to assess sensitivity to light touch, a posterior column function. A pin should be used to assess pain sensation, which is an anterior spinothalamic tract function. The presence of islands of preserved sensation within an affected dermatome or below the level of apparent total dysfunction, even in the presence of complete motor paralysis, indicates potential for functional motor recovery.[15] An accurate baseline sensory examination is imperative because a cephalad progression of hypesthesia is the most sensitive indicator of deterioration. When this is observed in the cervical region, one should anticipate impending respiratory failure and stabilize the airway.

Complete Spinal Cord Lesions

A *complete spinal cord lesion* is defined as total loss of motor power and sensation distal to the site of an SCI. Functional motor recovery is rare in a patient with a complete cord syndrome that persists for longer than 24 hours after the injury.[7] Before diagnosis of a complete cord syndrome, however, two points should be considered. First, any evidence of minimal cord function, such as sacral sparing, excludes the patient from this group. Signs of sacral sparing include perianal sensation, normal rectal sphincter tone, or flexor toe movement. The presence of any of these signs indicates a partial lesion, usually a central cord syndrome, and the patient may have marked functional recovery, including bowel and bladder control and eventual ambulation.

Second, it is important to note that a complete spinal cord lesion may be mimicked by a condition known as *spinal shock,* which may persist from a few days to a few weeks. Spinal shock results from a concussive injury to the spinal cord that causes total neurologic dysfunction distal to the site of injury.[16] The end of spinal shock is heralded by the return of the bulbocavernosus reflex, which is a normal cord-mediated reflex elicited by placing a gloved finger in the patient's rectum and then squeezing the glans penis or clitoris or by tugging gently on the Foley catheter. An intact reflex results in rectal sphincter contraction. Absence of this reflex indicates the presence of spinal shock, during which time the patient's prognosis cannot be accurately assessed. A complete spinal cord lesion will remain unchanged after the cessation of spinal shock.

Incomplete Spinal Cord Lesions

Approximately 90% of incomplete spinal injuries can be classified as one of three clinical syndromes: the central cord syndrome, the Brown-Séquard syndrome, and the anterior cord syndrome (Fig. 43-21).[7] The most common is the *central cord syndrome,* often seen in patients with degenerative arthritis of the cervical vertebrae when their necks are hyperextended. The ligamentum flavum buckles into the cord, resulting in a concussion or contusion of the central gray matter in the most central portions of the pyramidal and spinothalamic tracts. Because fibers that innervate distal structures are located in the periphery of the spinal cord, the upper extremities are more severely affected than the lower extremities. With more severe injuries, patients may appear to be almost completely quadriplegic and have only sacral sparing. The prognosis is variable, but more than 50% of patients with central cord syndrome become ambulatory and regain bowel and bladder control, as well as some hand function.[15]

The *Brown-Séquard syndrome,* or hemisection of the spinal cord, usually results from penetrating trauma but may also be seen after lateral mass fractures of the cervical spine. Patients with this lesion have ipsilateral loss of position and vibration sense as well as motor paralysis but contralateral loss of pain and temperature sensation distal to the level of injury; however, either finding may predominate depending on the exact location and extent of injury. Moreover, because the fibers of the lateral spinal thalamic tract cross at a different level to the contralateral side, the pain and temperature loss may be found variably one or two segments above the lesion. Virtually all patients maintain bowel and bladder function and unilateral motor strength, and most become ambulatory.[7]

The *anterior cord syndrome* usually results from hyperflexion injuries causing cord contusion, by the protrusion of a bony fragment or herniated disk into the spinal canal, or by laceration or thrombosis of the anterior spinal artery. It can also occur

www.ketabpezeshki.com 66485457-66963820

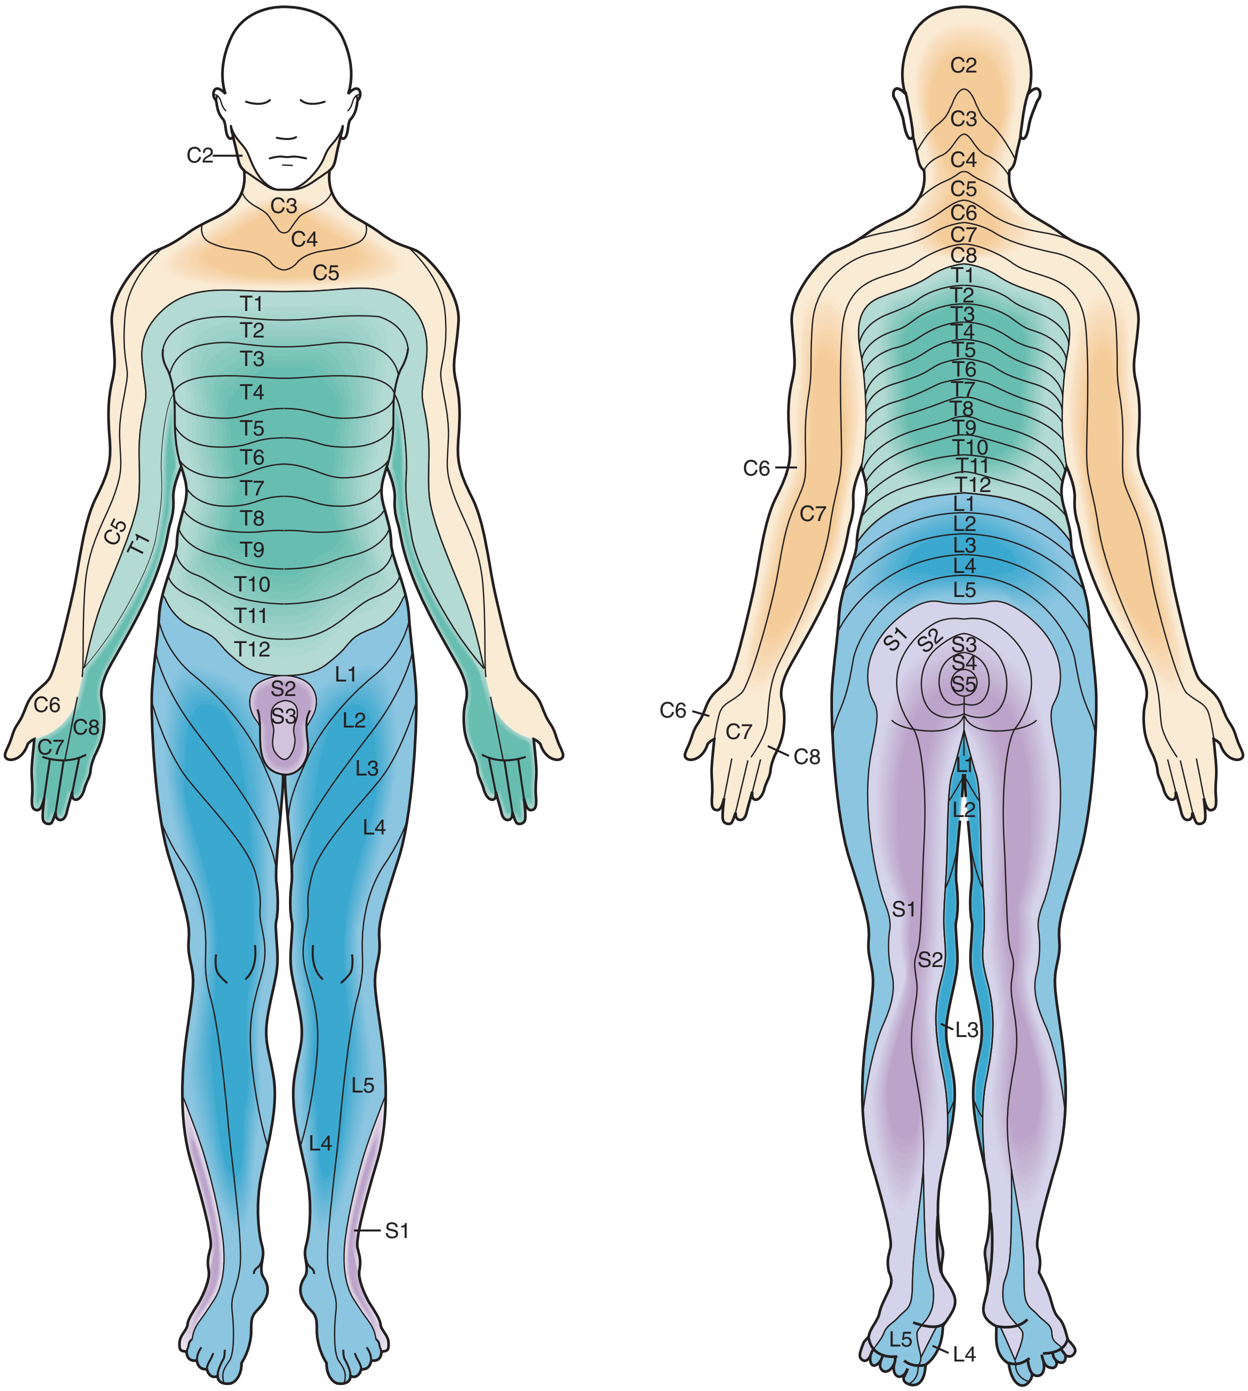

Figure 43-20. Sensory dermatomes.

after prolonged (longer than 30 minutes) cross-clamping of the aorta. This syndrome is characterized by paralysis and hypalgesia below the level of injury with preservation of posterior column functions, including position, touch, and vibratory sensations. Suspicion for an acute anterior cord syndrome warrants immediate neurosurgical consultation because it may be a result of a surgically correctable lesion. After surgical intervention, patients have variable degrees of recovery during the first 24 hours but little improvement thereafter.[7]

There are several less common spinal cord syndromes that may result from a direct injury to the cervicomedullary junction and upper cervical segments or from vertebral artery occlusion resulting from severe hyperextension (Fig. 43-22).[7] The *posteroinferior cerebellar artery syndrome* may produce dysphagia, dysphonia, hiccups, nausea, vomiting, dizziness or vertigo, and cerebellar ataxia. The *Dejeune onion skin pattern* of analgesia of the face is caused by damage to the spinal trigeminal tract. *Horner's syndrome* results from damage to the cervical sympathetic chain and is characterized by ipsilateral ptosis, miosis, and anhidrosis. Injuries below the L2 level can result in an *acute cauda equina syndrome,* characterized by perineal or bilateral leg pain, bowel or bladder dysfunction, perianal anesthesia, diminished rectal sphincter tone, and lower extremity weakness.

The syndrome of SCIWORA is seen primarily in younger children but may occur in any age group.[17-19] The mechanism is unclear but has been ascribed to the increased ligamentous

elasticity seen in the young, leading to transient spinal column subluxation, stretching of the spinal cord, and vascular compromise. Patients often experience a brief episode of upper extremity weakness or paresthesias followed by neurologic deficits that appear hours to days later. The prognosis for patients with SCIWORA is variable, depending on the degree of neurologic impairment and the rate of resolution.

DIAGNOSTIC STRATEGIES

Radiographic Evaluation

Indications

Clinicians have historically taken a liberal approach to imaging the cervical spine in the setting of trauma because failure to recognize an SCI may result in devastating neurologic consequences. According to the National Hospital Ambulatory Medical Care Survey, only 4% of all cervical spine radiographs demonstrate a fracture.[20] However, there is controversy as to what is the most efficient and accurate method of imaging, leading to great practice variation among emergency physicians, with a sixfold range in radiography ordering rates.[21]

In an effort to standardize clinical practice and guide physicians to be more selective in their use of radiography without jeopardizing patient care, two clinical decision rules have been developed. Use of selective but safe imaging may decrease overall health care costs, reduce radiation exposure, and avoid the discomfort and complications (e.g., aspiration and decubitus ulcerations) associated with patients lying flat on backboards with rigid collars while waiting for spine imaging. The first rule to be developed, the National Emergency X-Radiography Utilization Study (NEXUS) Low-Risk Criteria (NLC), was based on a multicenter prospective observational study involving 34,069 trauma patients seen at 21 U.S. emergency departments. The decision instrument required

www.ketabpezeshki.com 66485457-66963820

patients to meet five criteria to be classified as having a low probability of injury: (1) no midline cervical tenderness; (2) no focal neurologic deficit; (3) normal alertness; (4) no intoxication; and (5) no painful, distracting injury. The decision rule identified all but eight of the 818 patients who had spinal injuries. Only two of these patients had a clinically significant injury, only one of whom required surgical stabilization, and neither sustained a permanent neurologic injury.[22] Sensitivity, specificity, and negative predictive value of the NLC were calculated and were found to be 99.6, 12.9, and 99.8%, respectively.[22]

Owing to concerns about the low specificity of the NLC, Stiell and colleagues developed the Canadian C-Spine Rule (CCR) based on 25 selected clinical predictor variables associated with spine injury. In 2003 the CCR was prospectively studied and compared with the NLC in the nine Canadian tertiary care hospitals. Of 8283 patients, 162 were found to have "clinically significant" injuries, and the sensitivity, specificity, and negative predictive values of the CCR were, respectively, 99.4, 45.1, and 100%.[23] The CCR is composed of the following three questions:

1. Are there any high-risk factors that mandate radiography?
2. Are there any low-risk factors that allow safe assessment of range of motion?
3. Is the patient able to actively rotate his or her neck 45 degrees to the left and right?

High-risk factors include age older than 65 years, a "dangerous mechanism of injury" (a fall from a height >1 m, an axial loading injury, high-speed MVC [>100 km/hr], rollover, ejection, motorized recreational vehicle or bicycle collision), or the presence of paresthesias. Low-risk factors include simple rear-end vehicle crashes, sitting position in the emergency department, ambulatory at any time, delayed onset of neck pain, and the absence of midline neck tenderness. Although the NEXUS criteria are more widely used in the United States, both studies recommend obtaining cervical spine radiographs only for patients in whom spinal injury is clinically suspected.

There is some controversy as to which of the two rules to implement. There are methodological differences in the respective study designs, such as different inclusion and exclusion criteria.[23] Note that both studies excluded patients with penetrating trauma and those who had sustained direct blows to the neck. Still, both rules have been well validated and are sensitive, and the use of either rule has been shown to significantly limit the number of unnecessary radiographs while missing only rare patients with clinically significant injuries.

Cervical Plain Radiographs

Normal cervical spine radiographs in AP, lateral, swimmer's, oblique, and odontoid views are presented in Figures 43-23 and 43-24. All vertebrae suspected of being injured must be visualized. The C7-T1 vertebra may be obscured in muscular or obese patients, as well as in patients with spinal lesions that result in paralysis of the muscles that act to depress the shoulders. The paralysis leaves the trapezius muscles, which elevate the shoulders, unopposed. Such lesions are located in the lower cervical region. The shoulders can usually be depressed by pulling the patient's hands toward the feet, using slow, steady traction, but caution is exercised to avoid causing or worsening a distraction injury. Movement should occur only at the shoulder girdle while the head and neck remain immobilized. Note that the head and neck should not be pulled in opposition to the person pulling down the shoulders because this may induce a distraction injury. If this maneuver is unsuccessful or difficult to perform because of upper extremity injuries, a transaxillary or swimmer's view of the lower cervical vertebrae may be helpful. The upper three or four thoracic vertebrae are also difficult to visualize on routine lateral views of either the cervical or thoracic spine, and a swimmer's view, an oblique radiograph, or CT is often needed for adequate evaluation of the thoracic spine.

Although the cross-table lateral view of the cervical spine is the most helpful x-ray study in diagnosing spinal injures, its inadequacy as the sole view is well documented.[24] Because the diagnostic yield is significantly increased when the AP and odontoid views are included, all three views of the cervical spine should be evaluated before discontinuation of cervical spine immobilization.[25] The NLC shows that a technically adequate three-view trauma series will fail to diagnose spinal injury in only 0.07% of patients with injuries and in only 0.008% of patients with unstable injuries.[26]

Cross-Table Lateral View. The inspection of the lateral cervical spine film should be methodical and complete. For this to be accomplished, it is helpful to remember the "ABCs" of interpreting the lateral film, where *A* stands for alignment, *B* for bony abnormalities, *C* for cartilage-space assessment, and *s* for soft tissues.

For the alignment to be checked, two imaginary lines are drawn that separately connect the anterior and posterior margins of the vertebral bodies, the anterior and posterior contour lines. A third line, the spinolaminal line, connects the bases of the spinous processes extending to the posterior aspect of the foramen magnum (Fig. 43-25). All three lines should form a smooth, continuous lordotic curve, and any disruption of these lines suggests a bony or ligamentous injury. An exception to this rule is the pseudosubluxation of C2 and C3, which is commonly seen in infants and children. This phenomenon is attributed to their immature muscular development and a hypermobile spine. Thus if a high cervical injury is suspected in a child, the posterior cervical line, which connects the points bisecting the bases of the spinous processes of C1 and C3, should be used (Fig. 43-26). If the base of C2 lies more than 2 mm anterior or posterior to the posterior cervical line, an injury at that level should be suspected.[27] On the lateral view, the predental space, which is the distance between the anterior aspect of the odontoid process and the posterior aspect of the anterior ring of C1, should not exceed 3 mm in an adult or 5 mm in a child (see Fig. 43-26). A widening of this space may indicate a Jefferson fracture of C1.

Next, bony abnormalities should be assessed. Subtle changes in bony density should be noted. Areas of decreased density, seen in patients with rheumatoid arthritis, osteoporosis, or metastatic osteolytic lesions, are more apt to succumb under stress. Acute compression fractures of the vertebral bodies and metastatic osteoblastic lesions result in areas of increased bone density.

The emergency physician may diagnose subluxations and dislocations through cartilage-space assessment. A slight anterior or posterior widening of the intervertebral space or the interspinous space may be the only clue to an unstable dislocation.

Finally, the soft tissues of the retropharyngeal space should be assessed for the presence of prevertebral swelling and hemorrhage, often the only radiographic sign of spinal injury. The retropharyngeal space, measured from the anterior border of the body of C2 to the posterior wall of the pharynx, should not exceed 6 mm in children or adults (Fig. 43-27A and C). At the level of C3 and C4, this measurement should not exceed 5 mm or should be less than one half the width of the vertebral body at that level. Below the level of C4, the prevertebral soft tissue space is widened by the esophagus and the cricopharyngeal muscle. Here, the retrotracheal space, measured from the anterior border of the body of C6 to the posterior wall of the trachea, should not exceed 22 mm in adults or 14 mm in children younger than age 15 years. In children younger than age 2 years, the retropharyngeal space may normally appear widened during expiration; therefore inspiratory films

should be obtained.[28] Air in the prevertebral space may indicate rupture of the esophagus or some portion of the respiratory tree, and anterior bulging of the prevertebral fat stripe is an excellent sign of an underlying bony or soft tissue injury.

Odontoid View. The second film obtained in the emergency department is the open-mouth or closed-mouth view of the atlas and axis (see Fig. 43-24G-J). Nonfusion of the odontoid in children and congenital anomalies of the odontoid in adults may mimic fractures.

Anteroposterior View. The AP spinal film completes the spinal series. The spinous processes should form a straight line, and the laryngeal and tracheal air shadows should be midline (see Figs. 43-23B and 43-27D). The regular outline of the lateral masses should be verified, and the pedicles viewed end on can be checked for fracture. Widening of the interpedicular distance compared with adjacent vertebrae suggests a burst fracture (Fig. 43-28).

In addition to searching for fractures of vertebral bodies and transverse processes, bulging of the mediastinal stripe may be the only evidence of a thoracic vertebral body fracture. Fractures of the upper thoracic vertebrae may cause a posterior mediastinal hemorrhage that produces mediastinal widening on the chest x-ray film similar to that seen with aortic rupture.

Oblique Views

Oblique views of the cervical spine may be helpful to confirm a suspected posterior laminar fracture, a unilateral facet dislocation, or a real subluxation.[29] However, with the advent of high-resolution CT, suspicion of these injuries on plain films ordinarily leads to CT rather than the obtaining of oblique views. The normal lamina appears as an intact ellipse (see Fig. 43-23E and F), and a posterior laminar fracture disrupts the appearance of this ellipse (Fig. 43-29). Normal overlapping laminae have the appearance of shingles on a roof (see Fig. 43-27A and B). Integrity of these shingles excludes the presence of a unilateral facet dislocation, whereas disruption confirms it (see Fig. 43-11E and F). The normal interlaminar distance, measured from the center points of successive laminar ellipses on an oblique view, should be equidistant. An increased interlaminar distance, caused by lack of capsular ligamentous integrity, indicates true subluxation (Fig. 43-30).

Flexion and Extension Views

There is controversy as to the role of flexion and extension (F/E) views in blunt cervical trauma, but they are often obtained when there is concern for ligamentous injury, despite negative standard radiographs when magnetic resonance imaging (MRI) is not available. F/E views should be obtained only in patients who are alert and able to articulate the presence of pain, numbness, or paresthesias, because such symptomatology may indicate instability. Other potential indicators of instability of the cervical spine include any of the following: more than 3.5 mm of horizontal displacement between the disks, displaced apophyseal joints, widened disk spaces, loss of greater than 30% of the disk height, or the presence of a prevertebral hematoma.[30] The NEXUS investigators demonstrated that 86 of the 818 (10.5%) patients ultimately found to have cervical injury underwent F/E testing.[31] Although two patients had bony injuries and four patients had subluxations demonstrated only on F/E views, all 6 patients had other injuries apparent on routine radiographs. F/E views are also deemed inadequate for interpretation in nearly one third of studies.[32] In addition, in the acute setting, F/E radiographs have been reported to have unacceptably high false-positive and false-negative rates because minor subluxations may be masked by concomitant muscle spasm.[33] Thus delayed F/E views obtained a week or two after injury may be more helpful. Moreover, other studies, such as CT and MRI, appear to be superior imaging modalities in patients with severe, localized symptoms who have normal radiographs.[34]

Computed Tomography

Conventional radiography is limited as a result of the nature of equipment, difficulties in positioning, lack of patient cooperation, and the often critical status of trauma patients. The incidence of an inadequate lateral cervical view, specifically visualization of C7 to T1, is as high as 25%.[29] The CT scan effectively deals with these limitations and in many cases is the technique of choice for the definitive evaluation of acute cervical spine trauma.[35-38] CT also permits examination without moving the patient from the supine position and is thus preferable in terms of fracture stabilization, airway control, and other life-support measures. In fact, practice guidelines from the Eastern Association for the Surgery of Trauma (EAST) recommend that CT from the occiput to T1 be used as the primary screening method in blunt cervical trauma patients.[39]

www.ketabpezeshki.com 66485457-66963820

C and D, Normal relationship between soft tissues and bony structures of the cervical spine in the lateral and anteroposterior (AP) views. C, In the lateral view, the intervertebral spaces and interspinous spaces should be compared with the spaces above and below for asymmetry and important clues in flexion and extension injuries. The retropharyngeal and retrotracheal soft tissues are measured at the C2 and C6 levels for swelling. D, In the AP view, the tracheal and laryngeal air shadows should be within the midline. A straight line should connect points bisecting the spinous processes. If such is not the case, rotatory injuries are suspected.

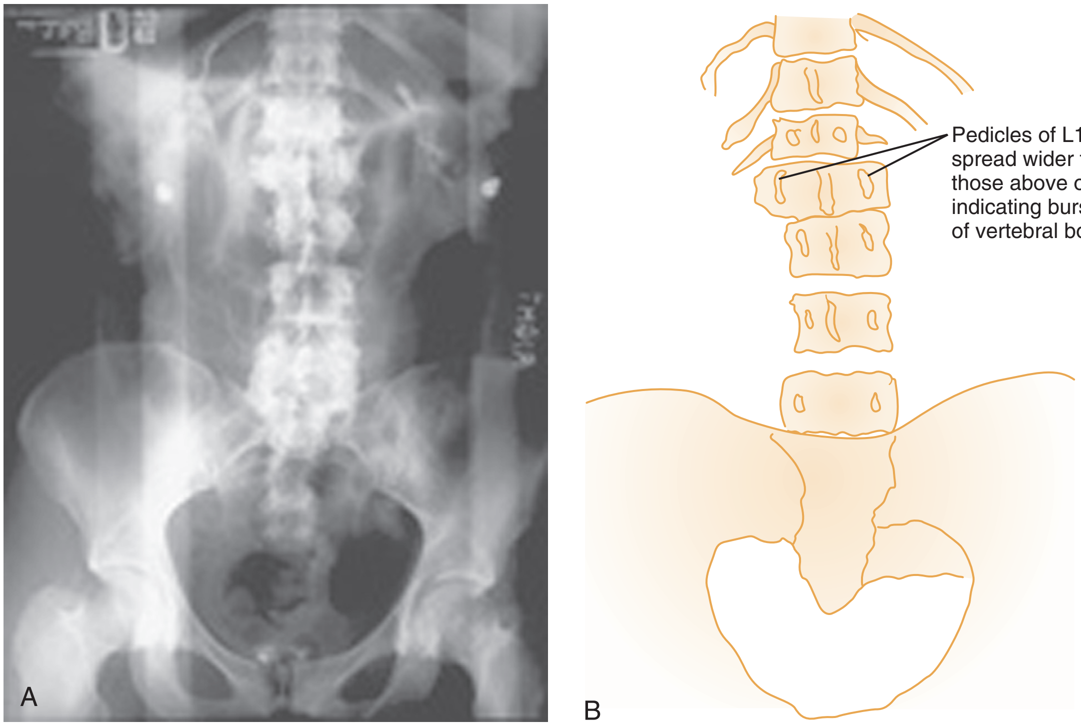

Figure 43-28. A and B, Burst fracture of L1. An anteroposterior radiograph shows increased distance between the pedicles of L1 in comparison to adjacent vertebrae. An intravenous pyelogram showed renal injury on the left.

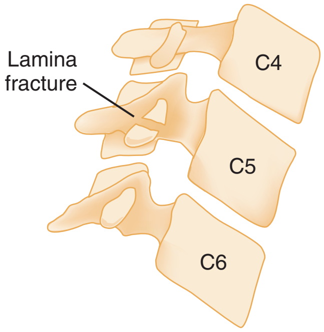

Figure 43-29. Oblique view of a laminar fracture. A fracture line extending through the lamina of C5 is well demonstrated on an oblique view.

The superiority of CT in fracture detection is a critical advantage (Figs. 43-31, 43-32, and 43-33); therefore unclear fractures or displacements on standard radiographs should be further evaluated by a CT scan. Because fractures in contiguous and noncontiguous vertebrae are fairly common, CT scan should be obtained to visualize the entire cervical spine. CT can also identify bony fragments, acute disk herniation, a foreign body, paraspinal hematoma, or an extramedullary hematoma.

A study comparing CT with plain radiography demonstrated the sensitivity in the detection of spine fractures to be 70% for plain radiography compared with 100% for CT, and there was a significant reduction in mean time in the radiology department with CT (1.0 vs. 1.9 hours, $P < .001$).[40] In another study, CT identified 99.3% of all fractures of the cervical, thoracic, and lumbar spine after high-energy trauma, and those missed by CT required minimal or no treatment.[41] Finally, a systematic review of studies comparing plain radiography and CT also demonstrated CT to be superior with a pooled sensitivity of 52% (95% confidence interval [CI] 47-56) for plain radiography versus 98% (95% CI 96-99) for CT.[42]

Owing to the advantages of CT, some authorities argue that routine plain radiographs of the spine are unnecessary when CT is readily available. Investigators have assessed whether vertebral images reconstructed from CT scans of the abdomen and pelvis obtained for the evaluation of chest and abdominal injuries provide sufficient data to screen for spinal fractures, thereby decreasing the time and cost of spine injury evaluation. CT is also thought to be adequate to clear cervical spines even in the obtunded blunt trauma patient.[43]

The spiral (helical) CT scan provides continuous acquisition of data (volume scan) via a rotating x-ray tube and simultaneous patient movement through the CT gantry (Fig. 43-34). The ability to reconstruct axial CT data in two-dimensional and three-dimensional formats is helpful to nonradiologists, who are less accustomed to performing the mental integration of multiplanar images (Fig. 43-35). The spiral CT scan can demonstrate cervical spine injuries not apparent on plain film or axial CT images (Fig. 43-36).

Potential disadvantages of CT include cost and radiation exposure. However, in one study, although CT was associated with higher mean overall spinal imaging charges than plain radiography ($4386 vs. $513, $P < .001$), there was no statistically significant difference when comparing spinal imaging cost per patient ($172 vs. $164, $P > .05$).[40] In the same study, radiation exposure for CT was higher than for plain radiography for cervical spine imaging (26 vs. 4 mSv), but CT had lower levels of radiation exposure for thoracolumbar imaging (13 vs. 26 mSv).[40]

Magnetic Resonance Imaging

CT has a higher sensitivity than MRI to detect fractures and dislocations at the craniocervical junction, as well as fractures of the posterior elements of the spine.[45] However, MRI, with its superior resolution and lack of ionizing radiation, also has the primary advantage of the ability to directly image nonosseous structures, including intramedullary and extramedullary spinal

abnormalities that potentially cause neurologic deficit (Fig. 43-37). Its major impact has therefore been in demonstrating potentially surgically correctable lesions, including acute disk herniation, ligamentous injury, bony compression, epidural and subdural hemorrhage, and vertebral artery occlusion (Fig. 43-38). MRI can identify three separate patterns of SCI, including acute cord hemorrhage, cord edema or contusion, and mixed cord injury. Patients with cord edema or contusion show significant neurologic improvement, whereas those with cord hemorrhage (Fig. 43-39) fare far worse. MRI therefore has diagnostic and prognostic capabilities in the evaluation of cervical spine injury. MRI is also viewed as the best diagnostic imaging modality for SCIWORA, in which MRI may demonstrate central disk herniation, spinal stenosis, cord edema, and contusion.

Contraindications to MRI include the presence of a pacemaker, cerebral aneurysm clips (MRI-compatible clips are now available), and metallic (ferromagnetic) foreign bodies. There are risks to performing an MRI, as well, such as aspiration, secondary brain

injury, and the difficulty of monitoring and resuscitating a patient in the MRI suite.[46] In addition, MRI cannot be used when MRI-incompatible life-support, monitoring systems, and cervical traction devices are employed (although MRI-compatible support systems exist). Plain films and CT are still superior to MRI in evaluating osseous anatomy and fractures, particularly posterior-element fractures.

The role of MRI in the evaluation of acute cervical spine trauma continues to evolve, and some advocate an immediate MRI in patients with clinical signs or plain film evidence suggesting ligamentous injury, particularly when prevertebral swelling is noted (Fig. 43-40). Most recommend MRI for patients with a strong clinical suggestion of an occult spine injury who have normal plain radiographs, including those with persistent neck pain or neurologic deficit. However, when CT findings are normal, some studies have demonstrated that MRI may not be necessary to exclude unstable injuries, even in the obtunded or "unreliable" patient.[47,48] A recent prospective study of the use of cervical spine CT in 402 obtunded patients reported a sensitivity of greater than 99%.[49] MRI, however, is useful in the evaluation of the previously traumatized spinal cord.[50] Progressive neurologic dysfunction in a previously stable cord-injury patient may indicate undiagnosed disk or bone impingement on the spinal cord, myelomalacia, a developing intramedullary (post-traumatic) syrinx, or subarachnoid cystic changes (Fig. 43-41), which can all be diagnosed by MRI. For fractures involving the transverse foramina or C1-C3, which are associated with vertebral artery dissection or thrombosis in up 22% of cases, as well as basilar artery stroke, magnetic resonance angiography (MRA), CT angiography (CTA), or four-vessel angiogram should be considered.[51]

MANAGEMENT

A spinal injury should be suspected in all trauma victims with an unknown or suggestive mechanism of injury associated with complaints of neck or back pain, evidence of significant head or facial trauma, spinal tenderness, signs of focal neurologic deficit, impaired consciousness, potentially distracting injuries, or unexplained hypotension (see Fig. 43-42 for management algorithm).

Spinal Column Stabilization

Out-of-Hospital Care

Paramedical personnel should suspect a spinal injury in any victim of trauma, especially those with craniofacial injuries caused by motor vehicle crashes, assaults, falls, and sports. Trauma victims may have an altered state of consciousness resulting from drug or alcohol intoxication, head trauma, or shock that makes cooperation difficult and spinal movement likely, unless steps are taken to immobilize the potentially traumatized spine.

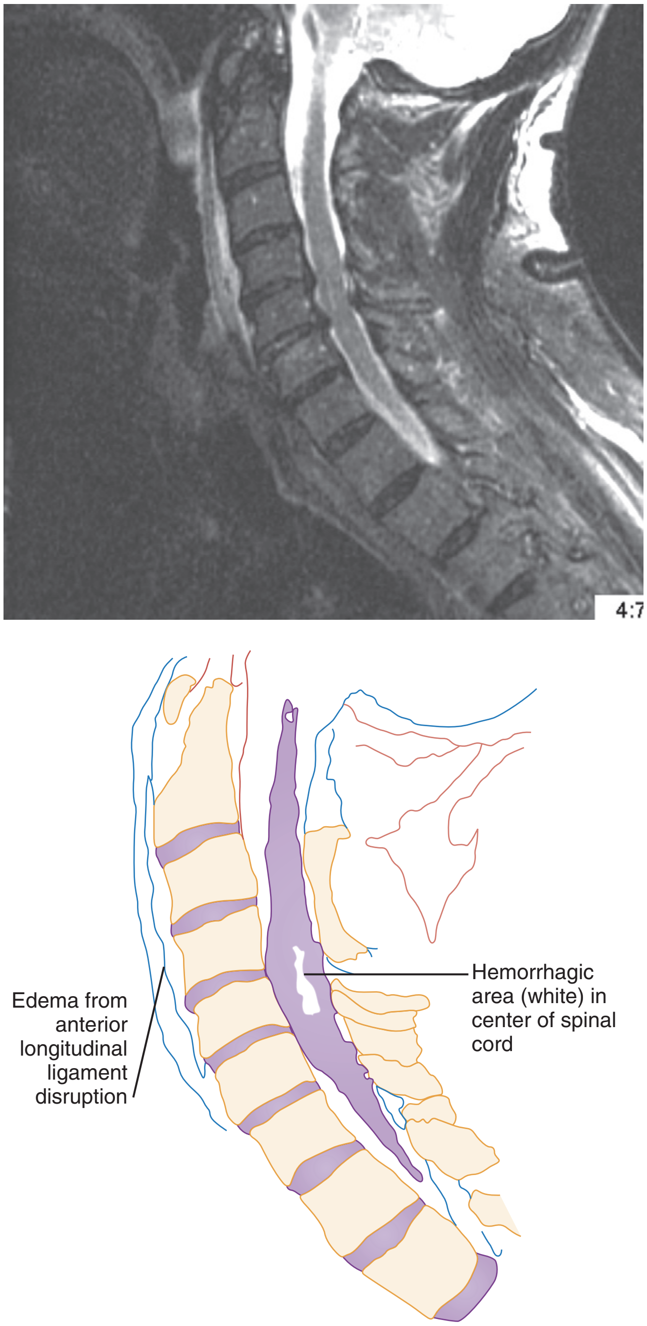

Figure 43-39. Magnetic resonance image showing a small area of central cord hemorrhage and both anterior and posterior ligamentous disruption.

Spinal immobilization should be initiated at the scene and maintained until a spinal injury is excluded in the emergency department. A variety of effective spinal immobilization orthoses are commercially available. The most widely used, and perhaps most effective, approach uses the combination of a spinal backboard, a rigid cervical collar, and supportive blocks placed on both sides of the head, which is held in place by straps or tape stretched across the forehead.[52-56] The heads of children younger than age 8 are somewhat large in proportion to their bodies, resulting in mild neck flexion when they are placed on a flat backboard. This can be avoided by use of a special backboard with an occipital recess or by placing a rolled sheet under the shoulders.[55] Further out-of-hospital care should be directed at evaluation and stabilization of associated injuries or problems requiring immediate intervention.

Emergency Department

Trauma victims who arrive at the emergency department with spinal immobilization should be quickly assessed by a physician. If the probability of spinal injury is moderate to high, it is advisable to remove the patient's clothes, evaluate any associated injuries, and perform resuscitative maneuvers without removing the immobilization apparatus. If the patient's spine can be clinically cleared by use of either the NEXUS criteria or the CCR, as described earlier, the immobilization device may be carefully removed. In addition, if the trauma victim was wearing a helmet and the helmet was not removed in the field, the face mask and/or the helmet may be carefully removed while immobilization is maintained.[56a] Ideally, at least two or three providers should be present to perform the task of helmet and face mask removal. The first provider should position himself or herself at the head of the bed and immobilize the cervical spine by placing both hands on the sides of the helmet while securing the patient's mandibles bilaterally. The chin strap should then be cut while a second provider takes over the job of in-line stabilization by placing one hand on the patient's occiput and another hand on the patient's chin. The first provider may then use a screwdriver to remove the four screws from the face mask and remove the face mask, which opens access to the airway. Note that face mask removal is all that is necessary to intubate the patient. The helmet and the shoulder pads should be removed simultaneously; one provider pulls the sides of the helmet away from the patient's ears while the second provider prevents hyperextension of the neck or overextension of the head onto the bed.[56b] Once the helmet and shoulder pads have been removed, a rigid collar should be placed if the patient's cervical spine cannot be cleared by use of the NEXUS criteria or the CCR.

Patients with probable spinal injury who are conscious and cooperative should be cautioned against attempted movement until radiographic studies have been performed. Patients who are uncooperative because of head injury, drug or alcohol intoxication, hypotension, or the presence of multiple painful injuries require a more aggressive approach, including consideration of the use of chemical sedation and mechanical restraints. Suspected thoracic and lumbar spinal injuries are best managed by keeping the patient supine and immobile. The goal of stabilization in cervical spine trauma is to immobilize both the neck and the body because any movement may extend the initial injury. If the patient is not already immobilized on a backboard, the torso should be firmly anchored to the examining table by straps or rolled sheets. A combative patient may require an assigned individual to hold the patient's head in alignment with the longitudinal axis of the body. Sedation, drug-induced paralysis, and intubation may be required for patients who pose a danger to themselves because of excessive movement. Spinal precautions should be maintained in patients with an altered sensorium until the presence of an injury can be excluded clinically or radiographically. Suctioning should be immediately available to prevent aspiration, and emergency department personnel must be aware of this ever-present possibility. When vomiting occurs, patients should immediately be placed on their side by logrolling, while spinal alignment is maintained, and suctioning performed.

Airway Management

The emergency physician should anticipate airway management problems in patients with cervical spinal injuries. Lesions above C3 may cause immediate respiratory paralysis, and the spread of edema from a lower injury may cause delayed phrenic nerve paralysis, as well as ascension of the neurologic injury above the level of C3. Cervical injuries may also be associated with airway obstruction from retropharyngeal hemorrhage or edema or maxillofacial

www.ketabpezeshki.com 66485457-66963820

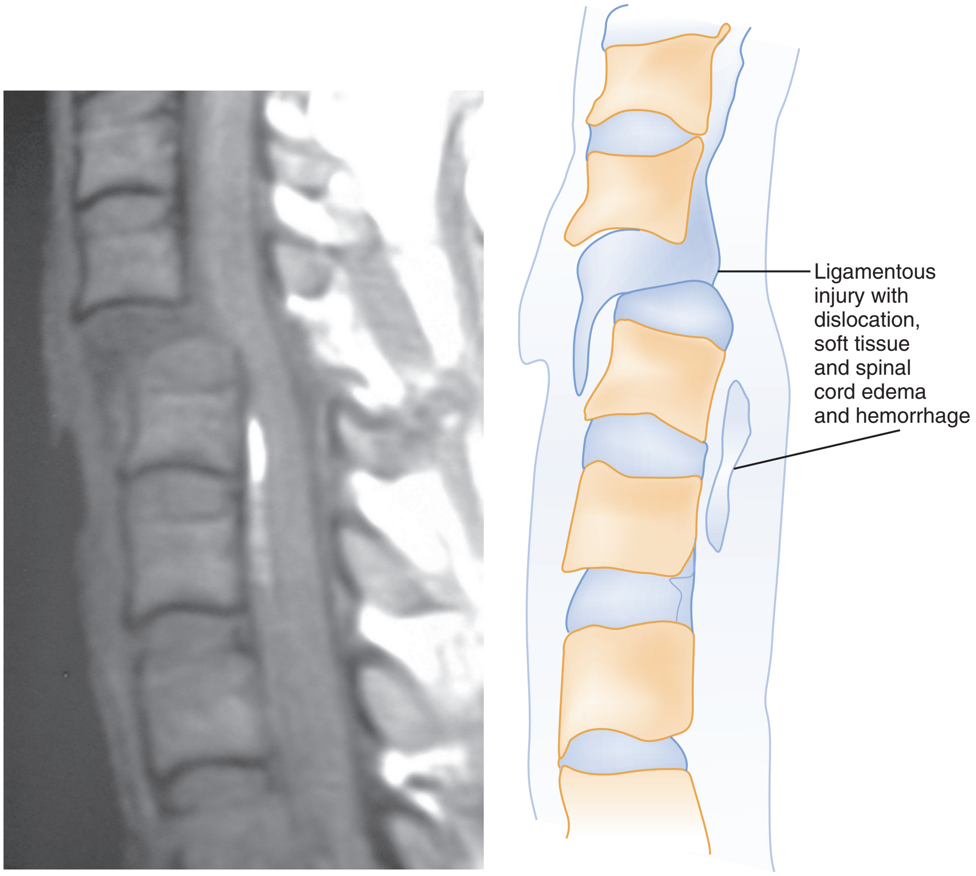

Figure 43-40. Anteroposterior longitudinal ligament disruption. A sagittal magnetic resonance image demonstrates ligamentous disruption between C4 and C5 with blood tracking in the anterior spinal canal.

trauma. In addition, acute pulmonary edema has also occurred after cervical spine injuries unassociated with significant head or chest injury.

According to the American College of Surgeons (ACS) Advanced Trauma Life Support guidelines, the preferred method of airway management for patients with traumatic cardiopulmonary arrest, even with evidence of spinal injury, is rapid sequence intubation (RSI) orotracheally with in-line spinal stabilization.[57] This is also the recommended approach for patients who are breathing but unconscious and in need of airway control or ventilatory support.[58-67] Hypoxia should be prevented, as it may contribute to apoptosis and further cord damage.[68]

The value of in-line spinal stabilization has been questioned in a review of the topic that notes that the data supporting its use come from cadaver studies, observations on uninjured volunteers, and several case series; that there is little evidence to support the contention that orotracheal intubation without in-line stabilization, which causes less spinal motion than the chin thrust maneuver, is unsafe in spinal-injured patients; that the incidence of spinal injury in trauma patients requiring intubation, who often have intracranial injuries, is quite low; and that there is evidence that in-line stabilization diminishes the laryngoscopic view, possibly leading to failed intubation and severe hypoxemia, which has been shown to predict poor outcomes in central nervous system injury.[69] The authors note that despite this information, clinicians will be hesitant to forgo in-line stabilization because it is recommended by the ACS and suggest that further studies in trauma airway management be performed with use of intubating supraglottic airways, optical stylets, and videolaryngoscopes. Cricothyrotomy or percutaneous jet ventilation should be considered for patients with severe maxillofacial injuries and when RSI is contraindicated or if attempts at orotracheal intubation fail (see Chapter 1).

Spinal Shock

Spinal shock is a clinical syndrome characterized by the temporary loss of neurologic function and autonomic tone below the level of an acute spinal cord lesion.[16] Patients usually exhibit flaccid paralysis with loss of sensation, deep tendon reflexes, and urinary retention, along with bradycardia, hypotension, hypothermia, and intestinal ileus. The cessation of spinal shock, which may last from less than 24 hours to more than 2 weeks,[70] is heralded by the return of the bulbocavernosus reflex.

Neurogenic hypotension secondary to spinal shock, caused by loss of vasomotor tone and lack of reflex tachycardia from disruption of autonomic ganglia, is a diagnosis of exclusion in the trauma victim. It should not be considered the cause of hypotension unless the patient is flaccid and areflexic; reflex tachycardia and peripheral vasoconstriction are absent; and, most important, the possibilities of coexisting hemorrhagic shock, cardiac tamponade, or tension pneumothorax have been eliminated. The absence of vasomotor activity in patients experiencing neurogenic hypotension can mask the usual presentation of these life-threatening injuries.

Although there is no consensus in the literature regarding the most appropriate treatment of neurogenic hypotension, it is prudent to begin the resuscitation of all newly arrived, hypotensive trauma victims with crystalloid fluid infusion. Most cases of pure neurogenic hypotension are mild (e.g., systolic blood pressure >90) and will initially respond to fluids. Severe (e.g., systolic blood pressure <70) neurogenic hypotension, seen in 20 to 30% of all patients with spinal injuries, usually occurs with high cervical injuries associated with total or near-total loss of neurologic function.[16] Hypotension can lead to hypoperfusion and secondary ischemic injury of the spinal cord, which can adversely affect prognosis. Therefore prolonged, severe hypotension must be prevented and treated.[71] Fluid resuscitation is often ineffective in such patients and may result in fluid overload if aggressively pursued. As a result, symptomatic neurogenic hypotension should be managed with fluids, Trendelenburg positioning (unless contraindicated because of concomitant head injury), vasopressors, or cardiac pacing—based on hemodynamic monitoring—once the diagnosis is established and other causes of traumatic shock have been excluded.

Pharmacologics for Incomplete Cord Injury

Experimental animal models of SCI support the concept that delayed biochemical damage, occurring hours to days after an initial traumatic insult, contributes to ongoing tissue loss and worsening neurologic function. As a result, numerous neuroprotective and neuroregenerative treatment strategies, including induction of hypothermia, have been investigated in both laboratory animal studies and human clinical trials (Box 43-1).[72-89]

Methylprednisolone is currently the only agent used for human victims of SCI outside of the research setting, and its use is highly controversial. The National Acute Spinal Cord Injury Study (NASCIS) investigators published several flawed studies showing that early administration of high-dose methylprednisolone improves the neurologic outcome of SCI victims.[77-80] Methylprednisolone is administered as an initial 30 mg/kg intravenous bolus followed by an infusion of 5.4 mg/kg/hr. The infusion is maintained for 24 hours in patients who are treated within 3 hours after injury, and it is maintained for 48 hours in patients who are treated within 3 to 8 hours after injury. The administration of steroids resulted in a worse outcome when started after 8 hours.

The NASCIS studies have been criticized for methodological flaws and for failing to assess whether the mild neurologic improvement seen in patients treated with methylprednisolone actually results in improved day-to-day functioning.[90,91] Moreover, other studies have reported that patients treated with methylprednisolone have a higher rate of infectious, gastrointestinal, and metabolic complications compared with placebo.[92] The most recent guidelines published by the Consortium for Spinal Cord Medicine (which includes the American Association of Neurological Surgeons, the American College of Emergency Physicians, the Congress of Neurological Surgeons, the American Association of Orthopaedic Surgeons, and the International Spinal Cord Society) in 2008 state that "no clinical evidence exists to definitively recommend the use of any neuroprotective pharmacologic agent, including steroids, in the treatment of acute SCI to improve functional recovery."[93] Despite this, the *Cochrane Database* review maintains that "high-dose methylprednisolone steroid therapy is the only pharmacologic therapy shown to have efficacy in a Phase Three randomized trial when it can be administered within 8 hours of injury…and…there may be additional benefit by extending the maintenance dose from 24 to 48 hours if treatment is not started until between 3 and 8 hours after injury."[94] Surveys performed in

Box 43-1 Treatment Strategies for Acute Spinal Cord Injury Currently under Investigation

A. Reduce the effects of the damage
 1. Maintain circulation
 2. Maintain oxygenation
 3. Reduce neurotoxins and free radicals (methylprednisolone, glutamate receptor antagonists)
 4. Reduce inflammation (cytokine, Rho, interleukin-10, tumor necrosis factor blockers)
 5. Reduce apoptosis (nitric oxide inhibitors, calpains)
 6. Cooling with induction of hypothermia
B. Encourage correct neuron function and connections
 1. With cells
  a. Schwann cells
  b. Olfactory ensheathing glial cells
  c. Astrocytes
  d. Reengineered fibroblasts
  e. Macrophages
  f. Oligodendrocyte precursors
  g. Electrical stimulation
 2. With matrix modifiers
  a. Netrins
  b. Neural glues (polyethylene glycol [PEG], synthetic hydrogels)
 3. With nerve grafts
  a. Peripheral nerve implants
C. Enhance regeneration and axon growth
 1. Inhibitor neutralizing antibody
  a. Anti-Nogo
 2. Neurotrophin-3
 3. Acidic fibroblast growth factor
 4. Brain-derived neurotropic factor
 5. Rho antagonists
D. Replace lost nerve cells
 1. Fetal tissue
 2. Stem cells
E. Inhibit scar and gliosis formation
 1. Decorin
 2. Chondroitinases
F. Reduce neurocircuit deficits
 1. Potassium channel blockers
 2. Sodium channel blockers
 3. Glutamate receptor blockers

Adapted from Cappuccino A, et al: The use of systemic hypothermia for the treatment of an acute cervical spinal cord injury in a professional football player. Spine (Phila Pa 1976) 35:E57, 2010.

the United States, the United Kingdom, and Canada between 2006 and 2009 reveal the number of spine surgeons using steroids to treat patients with blunt SCI diminishing to a minority in recent times, with many of those still using steroids listing "fear of litigation" as the reason.[93-96] Some authors continue to support the use of steroids until more effective treatments are discovered, feeling that the effectiveness of steroids in this setting has not been definitely disproved and that the majority of complications associated with steroid use in otherwise healthy young adults are most often minor and manageable.[97-101] There is currently no substantive scientific evidence to support the use of prednisolone for acute blunt SCI, and because of the possibility of severe complications and side effects[92,102,103] its use can be considered only, at best, a treatment option rather than the treatment standard. A risk-benefit assessment should be performed on a case-by-case basis.

Associated Injuries

Cardiopulmonary

Although deterioration in a trauma victim's cardiopulmonary status is usually the result of hemorrhagic shock or direct injury to the heart or lungs, it may reflect the development of pulmonary edema that occasionally occurs in response to brain injury and SCI.[104] Spinal cord trauma may stimulate an intense sympathetic discharge with two subsequent effects. First, pulmonary capillary endothelial cells are disrupted, leading to the pulmonary capillary leak syndrome, in which pulmonary edema occurs in the presence of normal pulmonary artery pressures (<18 mm Hg). Second, marked increases in afterload may cause left ventricular dysfunction, leading to pulmonary edema associated with a high pulmonary artery pressure (>18 mm Hg). Aggressive fluid resuscitation can also contribute to pulmonary edema. As a result, the management of such patients is often complex and requires carefully balancing fluid requirements, afterload-reducing agents, and artificial ventilation with positive end-expiratory pressure.[97] In addition, because of the autonomic dysfunction that often occurs in response to SCI, patients may demonstrate extremely volatile fluctuations in blood pressure, sometimes resulting in a life-threatening hypertensive emergency.

Gastrointestinal and Genitourinary

If SCI renders the abdominal examination unreliable, an abdominal CT scan, ultrasound, diagnostic peritoneal lavage, or some combination is often necessary.[105] In the acute stages of SCI, both the gastrointestinal tract and the bladder become atonic. Thus, once a patient has been stabilized, a nasogastric tube should be placed to prevent gastric distention, and a Foley catheter inserted to prevent bladder distention and to monitor fluid output. Because gastrointestinal bleeding from stress ulcers occurs in 2 to 20% of spinal trauma patients,[106] ulcer prophylaxis with histamine H_2 receptor antagonists or proton pump inhibitors should be initiated.[93]

Skin

Denervated skin is extremely susceptible to pressure necrosis, and sores can develop in less than 1 hour on unpadded spinal carts. Therefore backboards should be removed as soon as possible after spinal stabilization has been achieved. Padding pressure areas with sheepskin or foam padding early in the course of therapy can help minimize decubitus ulcers.

Definitive Treatment and Prognosis

The role of immediate surgical intervention in the management of spinal injuries is currently limited to relieving impingement on the spinal cord caused by foreign bodies, herniated disks, bony fracture fragments, or an epidural hematoma.[101,107] Surgery may be necessary later to stabilize severe bony injuries or to reduce spinal dislocations. The timing of surgical intervention is controversial, and there are no well-designed studies that have determined whether early (<12 hours) versus late decompression is beneficial.[93]

Once almost uniformly fatal, major spinal injury caused death as a result of pulmonary complications or sepsis resulting from skin necrosis or urinary infection. The advent of antibiotic therapy made long-term survival not only possible but also expected. Today, patients with SCIs are best managed by early referral to a regional spine injury center, where a team of neurosurgeons, orthopedic surgeons, psychologists, and physical therapists can initiate rehabilitation. Specialized SCI treatment centers offer patients a chance to return to a productive life within the limits of their disability. With the exception of patients with high cervical lesions (above C5), most patients attain sufficient independence to live outside of a high-level care environment.[109]

DISPOSITION

Cervical Sprain

Patients with musculoskeletal injuries of the spine who have only mild to moderate discomfort without neurologic impairment or abnormal radiographic findings are best managed as outpatients. Treatment should include analgesics and referral for follow-up evaluation. Up to 27% of patients experiencing neck pain in the emergency department after trauma will continue to have symptoms at 1 year.[110,111]

Minor Fractures

Most patients with spinal fractures require hospitalization. Patients with isolated cervical vertebral body compression fractures or spinous process fractures may be managed as outpatients if the mechanism of injury is not significant, there is no evidence of neurologic impairment or associated ligamentous instability, and the degree of patient distress is not severe. Appropriate follow-up should be arranged in all instances because even minor spinal injuries may be associated with prolonged disability resulting from chronic pain.[110-114]

For patients with minor wedge fractures (<10% wedge fractures) who do not have an associated ileus or neurologic deficit, outpatient management may also be possible. However, most wedge fractures of the thoracic and lumbar spine are usually best managed in the hospital for several reasons.[115,116] First, patients with these injuries usually have marked discomfort, often requiring parenteral narcotics. Second, significant force is generally required to fracture thoracic or lumbar vertebrae, and associated intrathoracic or abdominal injuries are common. Elderly patients who have vertebral fractures and only minor associated injuries may require admission to facilitate assessment of fall risks and to expedite rehabilitation. Finally, lower thoracic and lumbar fractures are associated with prolonged and occasionally delayed gastrointestinal ileus, requiring continuous nasogastric suction.

KEY CONCEPTS

- Victims of motor vehicle collisions, falls from heights, and sports-related injuries should have their entire spines examined for evidence of injury. Spinal radiographs should be obtained in the presence of suggestive symptoms or signs, or when an abnormal mental status or distracting injuries hamper clinical assessment.
- To prevent inadvertent movement of the spinal column, spinal precautions should be maintained in patients with altered mentation until the presence of a spinal injury can be excluded either clinically or radiographically.
- Evidence that high-dose methylprednisolone is a clinically efficacious intervention in the management of acute blunt partial SCI is lacking, and because of the possibility of severe side effects, its use can only be considered, at best, an option.
- Emergency department management includes prevention of secondary ischemic spinal cord injury by maintaining adequate oxygenation and avoiding hypotension; care should also be taken to prevent pressure ulcers, bladder distention, and gastric distention.

Chapter 44

Neck

Kim Newton and Ilene Claudius

PERSPECTIVE

Neck trauma can result in a spectrum of injuries and complications ranging from incidental to life-threatening, including hemorrhagic shock, acute neurologic injury, and airway obstruction. Vascular and laryngeal injuries can rapidly compromise the airway, challenging the most experienced physician. Stable-appearing patients may harbor insidious injuries associated with high morbidity and mortality if not recognized and treated in a timely manner. Emergency physicians should be familiar with neck anatomy, the spectrum of injuries and subtle presentations associated with neck trauma, as well as diagnostic evaluation, management controversies, and airway salvage techniques.

Neck trauma is divided into three major mechanisms: blunt, penetrating, and strangulation or near hanging. The injuries caused by these mechanisms can be further categorized into injuries of the airway (laryngotracheal), digestive tract (pharyngoesophageal), vascular system, and neurologic system. Each of these types of injuries has unique features and is discussed separately.

PRINCIPLES OF DISEASE

Pathophysiology

Penetrating Trauma

The incidence of neck trauma is reported to be 0.55 to 5% of all traumatic injuries. Neck trauma typically results from one of three major mechanisms: gunshot wounds (GSWs), stab wounds (SWs), and miscellaneous injuries, including impalement and shrapnel wounds.[1,2] GSWs are further divided into high-velocity and low-velocity injuries. High-velocity missiles include military-style weapons and hunting rifles that can achieve bullet velocities of 2000 to 3200 ft/s or greater. These missiles can easily penetrate soft tissue or bone. Their pathway is generally direct and predictable unless deflected, although they can also cause remote injuries through a blast effect. Bone penetration requires a minimum velocity of 350 ft/s. Low-velocity injuries (small-caliber handguns and air guns) are caused by missiles that travel at significantly slower velocities (e.g., 300 ft/s for .22-caliber pistols). Slower-moving missiles tend to produce erratic pathways, often demonstrating no direct relationship to the entrance or exit wounds.[3] Blast or cavitation effect pertains mainly to moderate- or high-velocity missiles (>1100 ft/s). *Cavitation* refers to the immediate release of kinetic energy as the bullet enters the tissue. This energy release causes temporary displacement of the surrounding tissue with cavity formation along the bullet's pathway. Cavitation can cause extensive soft tissue damage beyond that caused directly by the bullet.

The neck zone and mechanism of injury should be noted because lower-energy injuries (knife, handgun, or long-range birdshot or buckshot) cause a 50% lower incidence of clinically significant lesions (Fig. 44-1).[4] Zone I and III injuries pose a greater surgical challenge, and clinicians are more likely to order preoperative diagnostic tests to determine the best surgical approach (Table 44-1).[4]

SWs, being of very low velocity compared with missiles and most often limited to one side of the neck, are more amenable to nonsurgical management. Miscellaneous penetrating neck wounds can occur from any object capable of impalement, puncture, or laceration but most often result from glass fragments after motor vehicle collisions (MVCs) or from dog bites. The overall mortality rate for penetrating neck injuries is 2 to 6%, and the leading cause of immediate death is exsanguination.[1,5]

Blunt Trauma

Blunt neck trauma most frequently results from MVCs but can occur after assaults, "clothesline" injuries, strangulation, and sports injuries.[6] Blunt vascular injuries are rare[7] but represent some of the most underdiagnosed injuries seen by emergency physicians and trauma surgeons.[4] Blunt injuries to the aerodigestive and vascular tracts are uncommon compared with penetrating injuries but can cause acute airway compromise and serious delayed complications.

Anatomy

The neck is a complex, closed anatomic area dense with vital structures and invested with fascia creating several compartments. Because of this close anatomic relationship, vascular injury with hemorrhage may be tamponaded by fascial planes and neighboring structures but can lead to marked anatomic distortion, making evaluation and airway management extremely difficult. Two methods are used to describe the external neck: zones and triangles.[8] Anatomically, the neck has been divided into triangles (anterior and posterior). The *anterior triangle* is laden with vital structures (neurovascular and aerodigestive tracts) and is bordered anteriorly by the midline, posteriorly by the sternocleidomastoid muscle, and superiorly by the lower edge of the mandible. The *posterior triangle* is located within the boundaries of the sternocleidomastoid muscle anteriorly, the clavicle inferiorly, and the anterior border of the trapezius muscle posteriorly. Excluding spinal trauma, injury to this region often has a more favorable prognosis because of the relative paucity of vital structures.

Current practice favors division of the neck into zones I, II, and III. The widespread acceptance that many injuries span multiple

*Incidence based on other reported series.

zones means this anatomic description may be less helpful than previously thought. Zone division has both anatomic and management implications for penetrating neck trauma. *Zone I* (base of neck) extends superiorly from the sternal notch and clavicles to the cricoid cartilage. It includes the thoracic outlet below the cricoid cartilage. Injury to this region can affect both neck and mediastinal structures. *Zone II* (midneck) is the area between the cricoid cartilage and the angle of the mandible. Zone II injuries are therapeutically distinct because they lie in the most exposed region of the neck, making them accessible to direct surgical visualization with easier proximal and distal vascular control. *Zone III* (upper neck) extends from the angle of the mandible to the base of the skull. As with zone I injuries, proximal and distal vascular control in this region is difficult to achieve (Box 44-1).

Two fascial layers, the superficial fascia and the deep cervical fascia, cover neck structures. The superficial fascia covers the platysma muscle and is located just below the skin. The deep cervical fascia is divided into three parts: The *investing layer* surrounds the neck and splits to encase the sternocleidomastoid and trapezius muscles; the *pretracheal layer* adheres to the cricoid and thyroid cartilages and travels caudally behind the sternum to insert on the anterior pericardium; and the *prevertebral layer* envelops the cervical prevertebral muscles and extends to form the axillary sheath, which covers the subclavian artery. The pretracheal layer is clinically important because of its connection from the neck to the anterior mediastinum. Missed aerodigestive injuries can result in mediastinitis because of this anatomic continuity. The carotid sheath is made of portions from all three divisions of the deep cervical fascia. The *platysma muscle,* sandwiched between the superficial and deep cervical fascia, covers the anterolateral neck. It has clinical significance because of its superficial location and proximity to vital structures. If the platysma muscle is violated, injury to deep structures should be suspected, and by definition the injury is penetrating. Examination of any penetrating neck wound should document the zone or zones of injury and presence of platysma violation. Blind probing is discouraged as it may cause further injury or dislodge a clot and induce major hemorrhage.

CLINICAL FEATURES

Patients with neck injury can manifest numerous signs and symptoms, but most are nonspecific. This makes diagnostic strategies difficult, especially in the stable patient. Much debate in the current literature centers on the safest and most cost-effective approach for evaluating patients with possible neck injury. Serial examination is crucial to search for evidence of progressive airway or vascular compromise. Features that suggest decompensation in

Subcutaneous or mediastinal air
Chest tube air leak
Nonexpanding hematoma
Focal neurologic deficits

Hard Signs
Expanding hematoma
Severe active bleeding
Shock not responding to fluids
Decreased or absent radial pulse
Vascular bruit or thrill
Cerebral ischemia
Airway obstruction

a previously stable patient can include dyspnea, dysphonia, stridor, drooling, expanding hematoma, bruit, cerebral ischemia, or shock.

DIAGNOSTIC STRATEGIES

Researchers historically remained divided between those who did and those who did not believe that physical examination alone was adequate in determining which patients needed ancillary studies.[9-12] The literature is mixed on the sensitivity of physical examination for diagnosis of significant injury; however, a prospective series of 223 patients with penetrating neck wounds found that physical examination was reliable in determining which patients needed vascular or esophageal diagnostic studies.[9] Stable patients should be evaluated for the presence of "soft" and "hard" signs of aerodigestive or neurovascular injury (Box 44-2). Hard signs (expanding hematoma, severe active bleeding, fluid-nonresponsive shock, decreased or absent pulse, vascular bruit or thrill, cerebral ischemia, airway obstruction) indicate the need for emergent intervention. Soft signs (hemoptysis or hematemesis, oropharyngeal blood, dyspnea, dysphonia or dysphagia, subcutaneous or mediastinal air, chest tube air leak, nonexpanding hematoma, focal neurologic deficits) necessitate further evaluation but less commonly require surgical repair. Most patients with hard signs require surgical intervention. Controversy surfaced over the stable patient with soft or no signs of injury. Historically, management of penetrating neck trauma has undergone a similar evolution to trauma in other body regions in that management has progressed from a policy of mandatory exploration to one of selective management based on ancillary studies and serial physical examination.[13,14]

MANAGEMENT

Stable Patients

Ideally, stable patients with neck injury should be transported to a trauma center. Despite a stable initial appearance, airway compromise can ensue rapidly, and intervention is essential at the first sign of airway distress. Necessary interventions should be initiated during transport to the emergency department rather than at the scene to avoid delays in definitive care. Open wounds should be covered and sufficient compression applied to control bleeding and prevent air embolus without occluding the airway or blood flow to the brain. Consideration of cervical spine damage, especially in the face of blunt trauma or in the presence of neurologic deficits, should prompt the application of a cervical collar.

Unstable Patients

Airway

Airway management is the highest initial priority in the unstable patient. Cervical spine immobilization is typically unnecessary in penetrating neck trauma unless the patient has coexistent blunt trauma or evidence of a spinal cord injury. Oral intubation with rapid sequence intubation (RSI) is considered safe in most patients with neck trauma.[14,15] When the airway has been stabilized, breathing assessment is standard, with consideration of the associated risk of hemothorax or pneumothorax, seen primarily with penetrating zone I injuries.

Air Embolism

Caution is required when bag-valve-mask ventilation is necessary because air can be forced into injured tissue planes, resulting in massive subcutaneous emphysema and subsequent airway distortion or, rarely, air embolus.

Vascular Concerns

Wounds with active bleeding or blood clots should not be probed because massive hemorrhage can ensue. Ideally, bleeding is controlled by direct pressure. Blind clamping of active bleeding sites should be avoided because of the high concentration of neurovascular structures in the neck. If a vascular injury is suspected, mild Trendelenburg's position is recommended to reduce the risk of air embolism. Intravenous access is best placed on the uninjured side, avoiding the ipsilateral neck or upper extremity until vascular injury has been excluded.

Cervical Spine

Cervical collars might obscure neck pathology and preclude adequate examination. Partial removal of the collar while maintaining in-line stabilization may be necessary for adequate serial examinations to be performed.

Thoracotomy

The presence of profound shock or cardiopulmonary arrest unresponsive to fluids or emergency department thoracotomy should prompt the physician to consider venous air embolism (VAE). If this condition is suspected, the patient should be placed in a head-down, left lateral decubitus position to cause intracardiac air to accumulate in the apex of the right ventricle. If this maneuver alone does not improve cardiac output, aspiration of air from the apex of the right ventricle either by use of an ultrasound-guided pericardiocentesis needle or under direct vision after emergency department thoracotomy may be lifesaving. Evidence of cerebral ischemia, as manifested by profound alteration in consciousness or strokelike symptoms, suggests injury to the cervical vessels or cerebral arterial air embolism.

Nasogastric Tubes

Caution is advised in any patient with suspected vascular injury who requires a nasogastric tube (NGT). The retching typically seen with placement might dislodge a hematoma, resulting in immediate hemorrhage. If indicated, an NGT should ideally be placed after the patient has been intubated. Conversely, an NGT can be therapeutic if used to remove gastric contents to prevent

www.ketabpezeshki.com 66485457-66963820

aspiration, and it can be diagnostic because a bloody aspiration implies visceral injury.

Airway Management

Orotracheal Rapid Sequence Intubation

Although the ideal airway technique for neck trauma patients has been debated during the past decade, orotracheal intubation with RSI has been shown to be safe and effective and should be considered the first-line airway technique unless contraindications exist.[14,15] Orotracheal RSI is often successful even after neck trauma with airway distortion.[16] RSI has also been shown to be superior to intubation without neuromuscular blocking agents[17]; however, RSI medications should be used only by an experienced intubator. Concern that complete muscle relaxation would lead to airway collapse or that excessive movement might worsen unstable cervical spine fractures has not been borne out.[14,18] There are numerous alternatives for achieving intubation, but the emergency physician should be familiar with their limitations in the setting of neck trauma.[19] Less commonly used airway salvage techniques, however, may diminish the emergency physician's comfort level and prolong the airway stabilization procedure.

If the cervical spine must remain immobilized, an assistant should maintain in-line stabilization of the head and neck.[20] Relative contraindications to RSI include massive facial trauma or suspected laryngeal injury. When time allows, an initial inspection of the airway can be made with a laryngoscope in the awake patient. In cases in which orotracheal intubation is expected to be difficult, an attempt to intubate over a nasopharyngoscope may be prudent in patients who do not have massive bleeding into the oropharynx. All emergency physicians require a thorough knowledge of alternative techniques for intubation in the event that orotracheal RSI fails.[19,21,22] Nasopharyngoscopy, videolaryngoscopy, or surgical airways should be readily available if standard orotracheal intubation fails. In addition, it may be valuable to consult an anesthesiologist or otolaryngologist in the urgent situation if the patient remains stable.

Nasotracheal Intubation

Historically, nasotracheal intubation was recommended for the majority of trauma patients, especially if cervical spine injury was suspected. Early versions of the Advanced Trauma Life Support courses also taught that blind nasotracheal intubation (BNTI) was the procedure of choice in patients with neck trauma.[23] BNTI may have serious complications, including bleeding, vomiting, aspiration, increased intracranial pressure, turbinate damage, and sinusitis. In addition, if cervical spine injury has not been excluded, cervical protection can be difficult to maintain because of the retching and neck movement resulting from procedural discomfort often seen during BNTI in awake patients. Older studies have shown that success rates for BNTI range from 66 to 93%.[24] Although a more recent study demonstrated a 90% success rate with BNTI for trauma patients, it should be considered only in spontaneously breathing patients in whom other techniques described have been unsuccessful.[25] Nasotracheal intubation is contraindicated in those with suspected midface or basilar skull fractures or laryngeal injury but, barring contraindications, may be possible in an apneic patient with use of Magill forceps.

Surgical-Invasive Airways

Cricothyrotomy remains a common airway salvage technique used by many emergency physicians when endotracheal intubation is not possible.[19] Despite clear descriptions of this technique in the literature,[26] it is not always simple to perform. Anterior neck hematoma or potential laryngeal injury should make the intubator consider a different means of securing the airway because release of a tamponaded cervical hematoma may prove devastating. Although out-of-hospital cricothyrotomy performed by emergency medical services (EMS) personnel appears efficacious, controversy surrounds its safety.[27] Percutaneous transtracheal jet insufflation is an effective method of providing a temporizing airway but is not definitive and has potential complications, including inadvertent catheter dislodgment resulting in massive subcutaneous emphysema, catheter kinking, perforation of the posterior wall of the trachea and esophagus, pneumothorax, and hypercarbia. Performance of this procedure in a patient with complete upper airway obstruction can result in barotrauma from inadequate exhalation.[19,28]

Miscellaneous Techniques

Other airway techniques include fiberoptic laryngoscopy and bronchoscopy, which have been used successfully for difficult airways, although excessive bleeding can render visualization difficult. Lack of experience and time constraints are cited as reasons why these techniques are not preferred in the emergency department.[1,14] Emergency tracheostomy is not a common emergency department procedure because it is technically difficult and time-consuming to perform. It should be attempted only in select cases in which other techniques are contraindicated or not available. Although reported in the literature, esophageal obturator airway, retrograde intubation, laryngeal mask airway (LMA), and awake endotracheal intubation are generally not used as primary procedures or airway salvage techniques in trauma patients.[29,30]

Pediatric Considerations

Airway management in the pediatric trauma patient tends to be more anxiety-provoking, in part because of the different anatomic considerations. Ideally, the approach to the pediatric airway is similar to the adult airway, with use of orotracheal RSI. The incidence of unstable cervical fractures in children is lower than in adults.[31] As in adults, airway salvage techniques may be necessary, but fewer options are available in young children. The airway of the young child and infant is higher and more anterior, with the narrowest region of the airway at the cricoid cartilage.[32] The small cricothyroid membrane and the soft, poorly mineralized pediatric larynx make cricothyrotomy contraindicated in children younger than 10 years. Emergency tracheostomy, which is a difficult procedure in young children, or transtracheal jet ventilation can serve as a salvage technique.[33] Although the risks associated with transtracheal jet ventilation in adults are applicable to pediatrics, it is likely to be the quickest and safest surgical option in young children. BNTI in the infant and very young child is also not recommended, in part because the smaller endotracheal tubes are too pliable to be consistently passed.

Cervical Spine

Numerous papers have been written on the safety of orotracheal intubation in patients with known or suspected cervical spine injury.[16,20] Historically, cadaver studies generated fear of head movement during intubation, causing some to abandon the orotracheal route of intubation. However, RSI with in-line stabilization has not been shown to produce neurologic sequelae in humans and is believed to be a safe means of securing the airway in patients with both penetrating and blunt cervical trauma.[14,29] Neurologically intact patients with unstable cervical fractures secondary to penetrating trauma rarely manifest delayed neurologic sequelae.[5,34] There is greater concern for occult or overt cervical spine injury in the patient with blunt neck or multisystem trauma,

www.ketabpezeshki.com 66485457-66963820

although cervical spine injuries in this population are not as common as once thought. Armed with this knowledge and barring contraindications, emergency physicians should use the airway technique with which they are most comfortable. Delays in securing an airway because of indecision regarding which technique to use can lead to hypoxic brain injury and death.

Mandatory versus Selective Exploration

The debate is ongoing in the trauma literature concerning the best way to manage penetrating neck injuries. Before World War II, patients with penetrating neck trauma were treated expectantly rather than aggressively despite unacceptably high mortality rates (18-35%).[1] In an attempt to reduce the mortality associated with penetrating neck injuries, the concept of mandatory surgical exploration of all penetrating neck wounds was developed.[35] Mandatory surgery drastically reduced mortality rates to 6%.[4] Wartime experience justified the ongoing use of mandatory surgery in victims with penetrating neck injury, and this was widely accepted for decades.

Despite low mortality rates achieved with mandatory surgery, negative neck explorations concurrently increased 40 to 63% during the mid-to-late 1900s as many institutions adopted a mandatory surgical approach.[2] As with other traumatic injuries, an effort to reduce the negative exploration rate while maintaining low morbidity and mortality rates led to the concept of *selective surgical management,* which remains institution specific. Selective management offers a spectrum of approaches, ranging from serial physical examinations to an array of diagnostic tests in the stable patient. A selective approach is justified because (1) military injuries were often secondary to high-velocity missiles, as opposed to currently used weapons (e.g., knives and handguns) and animal bites; and (2) improved technology currently allows much greater accuracy in the detection of injuries. A review of zone II penetrating neck trauma cites similar overall mortality rates of 5.85% in the mandatory group and 3.74% in the selective group.[36] Current literature favors a selective approach, with the trend in the past decade being to minimize unnecessary invasive procedures.[37,38]

Transcervical Gunshot Wounds

Transcervical gunshot wounds (TC-GSWs) represent a subset of penetrating neck trauma and are included in the debate between mandatory and selective management schools. TC-GSWs are associated with a twofold-increased incidence of injuries compared with GSWs that do not cross the midline (79 vs. 31%). The most common injury seen is vascular (48%), followed by spinal cord (24%).[39] Although some centers still practice mandatory exploration for these injuries, prospective studies suggest that stable patients with TC-GSWs can be safely evaluated with a selective surgical approach with the appropriate diagnostic studies and frequent serial examinations.[39] GSWs in the anterior midline also involve an increased incidence of vascular and visceral injuries, and a more aggressive diagnostic approach should be considered in these patients.

DISPOSITION

Many patients in the emergency department with penetrating or blunt neck trauma have predetermined disposition, especially when their condition warrants further diagnostic studies, surgery, or intensive care. Most stable patients should be admitted for observation. All patients with platysma muscle violation should be admitted to the surgical service for ongoing observation, regardless of their stability. Careful observation should be maintained for patients with blunt neck injury because they can manifest delayed signs and symptoms of viscerovascular injury with serious consequences.

Because smaller hospitals may have neither the ancillary support nor the personnel to perform serial bedside examinations, mandatory exploration might be in the patient's best interest in these facilities. Level I trauma centers generally have sufficient ancillary support and diagnostic tools and are more suited to avoid surgery safely in stable patients. Patients deemed to be stable may be transferred to trauma centers via high-level EMS systems with particular expertise in airway management. Studies suggest that surgeons with trauma experience tend to perform fewer neck explorations.[20]

SPECIFIC INJURIES

Pharyngoesophageal Trauma

Epidemiology

Esophageal injuries are infrequently reported after penetrating neck trauma, representing only 0.11% of all trauma admissions.[40] Blunt esophageal perforation is even less common, with only 10 case reports in the literature before 1990. The low incidence of injury most likely results from the relatively protected position of the esophagus. The cervical esophagus is injured more often than the distal segment.

Pathophysiology

Early diagnosis of esophageal injury is crucial because spillage of orogastric contents with bacterial contamination can lead to florid inflammation, infection (abscess and mediastinitis), and death. Esophageal injuries represent the most frequently missed injuries in the neck,[34] and mortality from esophageal injuries has remained relatively high during the past two decades, with an overall rate of 19 to 22%.[35,40]

Clinical Features

Although there are no pathognomonic signs of esophageal injury, soft signs of injury include hematemesis, odynophagia, dysphagia, subcutaneous emphysema, and blood in the saliva or NGT. Other associated findings include dyspnea, hoarseness, stridor, cough, pain and tenderness in the neck, and resistance to passive neck movement.

Physical examination is considered unreliable in diagnosing esophageal injury, although one trial found no operative injuries without accompanying signs or symptoms.[9] Because timely diagnosis is very important, most believe that sole reliance on physical examination is not warranted in stable patients with soft signs of esophageal injury.[35,36]

Diagnostic Strategies

Unfortunately, esophageal injuries are difficult to diagnose. Timely diagnosis is believed to be associated with decreases in morbidity and mortality, with poorer outcomes found in patients treated beyond 24 hours from the time of injury.[35,37,40]

Diagnosing esophageal injury often depends on more than a high clinical suspicion. Plain films of the neck and chest radiographs are inadequate but may suggest esophageal perforation if pneumomediastinum or retropharyngeal air is present.[38,39] Contrast esophagography alone is considered relatively unreliable for diagnosing esophageal injuries, with a sensitivity of 80 to 89%.[40] This study requires adequate views for accurate interpretation and thus requires the patient's cooperation. Typically, a Gastrografin study is performed initially, followed by thin barium only if the

www.ketabpezeshki.com 66485457-66963820

Gastrografin study is negative; however, some authors recommend the use of water-soluble contrast as a safer alternative.[41] Flexible endoscopy has also been reported as insensitive, primarily missing proximal esophageal injuries because the scope is unable to efface the mucosa in this region.[4] Currently the combination of contrast swallow and flexible endoscopy appears to be accurate in diagnosing esophageal injuries, with one study demonstrating a sensitivity of 100%.[42] A prospective study suggested that only obtunded or symptomatic patients (hematemesis, painful swallowing, or subcutaneous emphysema) need studies to exclude esophageal injuries.[9] Many agree that only select populations should undergo a watch-and-wait approach and that the vast majority of patients with suspected esophageal injury need definitive diagnosis and treatment.[39]

The advent of the higher-resolution computed tomography (CT) scan may increase the sensitivity for penetrating zone II esophageal injuries and either supplement the physical examination in selectively managed patients or theoretically negate the need for other diagnostic studies.[43] However, sole reliance on this diagnostic modality in searching for esophageal injuries is currently not supported by the literature. Extravasation of contrast is rarely seen, and CT depends on visualization of indirect signs such as paraesophageal air or fluid, esophageal wall thickening, or edema.[44] CT scan can be useful to look at the wound track or trajectory of a bullet in the instance of penetrating trauma, thus helping to determine if a proximity wound is likely, but it has not been shown to be sensitive as a stand-alone diagnostic modality.[43,45]

Management

When esophageal injury is suspected, broad-spectrum antibiotics with anaerobic coverage should be administered, and the patient should receive nothing by mouth. Preoperative placement of an NGT under endoscopic guidance may reduce the spillage of gastric contents into the wound. Any uncontained perforation of the esophagus requires prompt surgical therapy, and small contained perforations may be candidates for observation and reimaging.[46] Esophageal stents are gaining popularity for certain nontraumatic perforations, and case reports exist for their use in trauma.[46] Isolated pharyngeal injury can be managed nonoperatively in the majority of cases.[38]

Laryngotracheal Trauma

Mechanisms of Disease

Laryngotracheal (LT) injuries account for less than 1% of all trauma injuries, with most confined to the cervical trachea. Most LT injuries result from direct blunt force sustained in MVCs, in which the extended neck strikes the steering wheel or dashboard and the larynx is compressed between the fixed object and the cervical spine. Other mechanisms leading to LT injuries include clothesline injuries, improperly fitting shoulder harnesses, near hanging, assaults, athletic events, attempted strangulation, and iatrogenic wounds. Penetrating LT injuries make up 10% of all penetrating neck trauma.[4] Associated cervical spine injuries should always be considered simultaneously, especially in evaluating a patient with blunt neck trauma.

The cricoid cartilage is the only complete solid ring in the larynx. Fractures of the cricoid cartilage can lead to death through acute airway obstruction and are the most serious laryngeal injuries. Calcification of the laryngeal cartilages begins during the teenage years, and fractures before this age are much less likely to appear on plain neck films. The degree of airway obstruction after blunt trauma to the larynx is inversely related to the degree of cartilage calcification, putting children at highest risk.

Clinical Features

There is no consensus on whether all surgically significant LT injuries will manifest clinically at the time of initial evaluation in the emergency department.[18,47] Bubbling or air leakage from a neck wound should signal injury to the respiratory tract and is considered a hard sign of LT injury. Massive subcutaneous air and bony crepitus over the larynx suggest LT injury, as does a clothesline mechanism.[48] Other clinical features of LT injury include dysphonia, aphonia, dyspnea, stridor, hemoptysis, subcutaneous emphysema, laryngeal crepitus, neck tenderness or pain over the larynx, a visible neck wound, or loss of anatomic landmarks secondary to hematoma. Pain with tongue movement implies injury to the epiglottis, hyoid bone, or laryngeal cartilage.[1] In one study, neck pain, hoarseness, and dyspnea were the most common signs of injury in children with LT trauma.[49] Others cite subcutaneous air found by examination or on radiographs and tenderness over the larynx or trachea as the most common findings.[50]

Diagnostic Strategies

Diagnostic evaluation options exist for the stable patient. Missed injuries can lead to long-term sequelae, including recurrent pneumonia, dyspnea, voice change, dysphagia, laryngeal stenosis, and chronic pain. Patients with penetrating trauma are managed by a mandatory or selective protocol. Plain radiographs should be evaluated for extraluminal air, edema, foreign bodies, and fracture of the cartilaginous laryngeal structures. Laryngoscopy or flexible nasopharyngoscopy allows direct evaluation of laryngeal integrity. With appropriate local anesthesia, laryngoscopy is well tolerated by most patients who remain in cervical spine immobilization, and it can detect hypopharyngeal tears. Rigid endoscopy is useful to evaluate injury distal to the larynx but requires general anesthesia.

Spiral CT scanning is a valuable adjunct, quickly providing detailed information about laryngeal integrity and the surrounding region.[45] Rather than reliance on a cervical spine CT, 1-mm cuts should be obtained and multiplanar reconstructions performed to optimize the study. Its sensitivity ranges from 85 to 100%, depending in part on whether presence of mediastinal or subcutaneous air is included as a diagnostic feature.[51,52] CT is more useful for detecting fractures of the hyoid bone, disrupted laryngeal or tracheal cartilages, significant exolaryngeal or endolaryngeal hematoma, and dislocations of the cricothyroid or cricoarytenoid joints and for assessing airway diameter and vocal cord integrity. CT is less useful for the detection of mucosal perforations, degloving injuries of the cartilage with denuded mucosa, and certain types of LT separation. Typically, injuries missed by CT scan are group 1 (minor hematoma or laceration) and 2 (edema, hematoma, minor mucosal disruption, or nondisplaced fracture) injuries, which would be unlikely to require surgical management.[53] CT may be less helpful in evaluation of poorly calcified pediatric cartilaginous structures.

Widespread access to ultrasound has led to an increase in its use for trauma patients. Some advocate ultrasound to detect blunt laryngotracheal injuries such as laryngotracheal separation; however, larger studies are needed to confirm the usefulness of this modality.[54]

Management

Airway compromise in patients with LT trauma can be immediate or delayed. Clinical judgment is exercised in patients who initially appear to have stable, patent airways if they are to be sent to other departments for further diagnostic testing. Delayed airway occlusion can be rapid and life-threatening, and these patients require

www.ketabpezeshki.com 66485457-66963820

close monitoring. Airway management controversies persist, and the question regarding the safest technique for intubation (orotracheal, cricothyrotomy, tracheostomy, fiberoptic scope, or adjuncts) is unresolved. If available, an awake, fiberoptic-guided oral intubation is likely the best route.[55,56] If this is not feasible given the status of the patient, the American College of Surgeons recommends a single attempt at orotracheal intubation before moving to a surgical airway.[23] Use of an ETT one size smaller than typical has been advocated owing to the potential for edema caused by the original trauma making intubation with a standard-sized tube difficult to impossible.[57] Nearly 70% of patients can be intubated in a standard fashion,[58] but the possibility of completing a partial LT separation or creating a false passage exists, and confirmation of tube placement is of paramount importance. No attempt at intubation with paralysis should be performed without the accessibility of a surgical airway. Tracheostomy is preferred over cricothyroidotomy because of the potential for the latter to further damage an injured larynx. In cases with a large neck wound, intubation can be performed through the wound, provided the trachea can be visualized.[59] If complete LT separation is present with distal retraction of the trachea, orotracheal intubation is likely to be unsuccessful, and tracheostomy might unknowingly be performed proximal to the tracheal segment. Tracheal hooks can be used to recover the distal end of the trachea, and tracheostomy performed at the fourth or fifth tracheal ring to avoid the larynx. BNTI or use of an LMA is discouraged in these injuries.[60] Because blunt LT injuries are often seen in association with multisystem trauma, they can be easily overlooked when other overt injuries are present, but these injuries in association with the need for emergent airway stabilization portend a higher mortality.[61]

Definitively, most small mucosal injuries, hematomas, and nondisplaced fractures can be managed conservatively with analgesia, humidified air, elevation of the head of the bed, antibiotics, steroids, antireflux medications, vocal rest, and a clear diet[60,62,63] Unstable patients or those with higher-grade injuries require surgical repair.

Vascular Trauma

The great vessels of concern in the neck include the carotid, subclavian, and vertebral arteries and the internal and external jugular veins. Injury to these vessels can produce morbidity and mortality through exsanguination, hematoma expansion with subsequent airway distortion and compromise, direct vessel injury leading to vascular occlusion, or embolization of a foreign body (e.g., shotgun pellet to brain or heart). Carotid artery dissection may follow even trivial neck trauma and can result in stroke in young, otherwise healthy patients. The presence of delayed-onset, evolving, central neurologic deficits in a patient with neck trauma should prompt assessment of the carotid arteries for dissection. Combined data from 16 studies of penetrating neck trauma during a 25-year period found that the carotid artery was the most commonly injured artery, with an incidence of 6.7%. This was followed by subclavian artery injuries (2.2% incidence) and vertebral artery injuries (1.3%).[4] Overall, the jugular vein is the most commonly injured of the neck vessels.[64]

Epidemiology

Penetrating Injury. Vascular injuries represent 25% of all penetrating neck wounds, and mortality rates range from 10 to 50%.[64] GSWs are more likely to be associated with hard signs of vascular injury than are SWs. Hard signs of vascular injury include pulsatile bleeding, rapidly expanding hematoma, bruit, shock unresponsive to fluid resuscitation, massive hematemesis or hemoptysis, or focal neurologic deficits consistent with carotid or vertebrobasilar arterial occlusion. Exsanguination from vascular injuries is the most common cause of immediate death after penetrating neck trauma.

Blunt Injury. Blunt carotid injuries affect 0.33 to 0.67% of blunt trauma victims.[65] Mortality rates for blunt cervical vascular injuries range from 31 to 59%.[66] Because the internal carotid artery is the most frequently injured artery, many studies use blunt vascular and carotid artery injuries synonymously, although the vertebral artery is injured in up to 15 to 20% of cases.[67,68] The actual incidence of blunt vascular injuries may be higher because of asymptomatic cases and difficulties in making the diagnosis. Blunt vascular injury should be suspected in patients with flexion-extension mechanisms, diffuse axonal brain injury, and midface, mandibular, or basilar skull fractures.[7] Vertebrobasilar arterial injuries may follow relatively minor trauma, such as chiropractic neck manipulation, but most commonly occur in association with fractures of the spinal column. Symptoms typically arise after a delay of hours to months with signs of posterior circulation embolus or infarction, and they portend a poor prognosis.

Pathophysiology

Penetrating Injury. Most cases of penetrating trauma in adults are caused by knife or bullet wounds.[9] Vessel damage most often results from direct injury, although the blast effect can cause intimal injury without directly striking the vessel, making the vascular insult similar to that seen with blunt trauma.

Blunt Injury. Blunt trauma to the cervical vessels can result in a spectrum of arterial injuries, including intimal tears, thrombosis, dissection, and pseudoaneurysm.[6,66] Embolization can occur from a thrombus that develops at the injury site. The most common mechanism for blunt internal carotid artery injury is sudden, forceful hyperextension and lateral rotation of the neck. This mechanism can cause stretching of the carotid artery over the transverse processes of the upper cervical vertebrae, resulting in intimal injury.[66] Other mechanisms responsible for this type of injury include direct blunt force to the side of the neck, intraoral trauma (e.g., children falling on lollipops), and basilar skull fractures involving the petrous or sphenoid portions of the canal, which have rarely been associated with injury to the intracranial portion of the carotid artery. Blunt carotid artery injuries most often result from MVCs but have also been reported after fights, athletic events, seat belt injuries, and strangulations.[65]

Clinical Features

The debate regarding whether the physical examination is sensitive enough to detect vascular injuries in stable patients with minimal signs and symptoms is unresolved. Angiographically documented arterial injuries have not been reliably detected by physical examination in some series.[67] Others argue that although discrepancies may exist, they are not clinically relevant in the asymptomatic patient and rarely change management, and thus these clinicians conclude that serial examinations are adequate.

Penetrating Injury. In a recent study of patients with penetrating neck trauma, 39 patients with hard signs of vascular neck injury (active hemorrhage, expanding or pulsatile hematoma, bruit or thrill, fluid-unresponsive shock, massive hemoptysis or hematemesis) or aerodigestive injury (air leaking through injury site) had a total of 38 vascular injuries that were identified. In 189 patients with soft signs of vascular injury (venous oozing, nonpulsatile, nonexpanding hematomas, minor hemoptysis) or nonvascular neck injury (dysphonia, dysphagia, subcutaneous emphysema), 16 patients were found to have vascular injuries. No injuries were identified in the 228 patients with neither hard nor soft signs either by CT-angiogram or observation, attesting to the potential

www.ketabpezeshki.com 66485457-66963820

for risk-stratification of penetrating neck trauma patients based on presence of hard and soft signs.[69]

Blunt Trauma. Specifically with regard to dissections from blunt trauma, approximately half of patients are asymptomatic. When symptomatic, carotid injuries cause contralateral sensory or motor deficits, and vertebral injuries cause ataxia, vertigo, emesis, and visual field deficits.[66] The Western Trauma Association suggests emergent diagnostic evaluation and management for any blunt neck trauma patient with arterial hemorrhage from the neck, mouth, or nose; any patient with a large or expanding cervical hematoma; patients older than 50 years with cervical bruit; and patients with focal or lateralizing neurological deficit, transient ischemic attack (TIA), Horner's syndrome, vertebrobasilar insufficiency, or evidence of infarct on imaging. Other patients at sufficiently high risk in whom screening is recommended include those with cervical hyperextension or hyperflexion with rotation, direct cervical trauma, intraoral trauma, basilar skull fracture involving the carotid canal, Le Fort II or III fracture, closed head injury with diffuse axonal injury and Glasgow Coma Scale score below 6, cervical vertebral body or transverse foramen fracture, any fracture at C1 to C3, cervical spine ligamentous injury, near hanging resulting in anoxia, seat belt or clothesline-type injury with significant cervical pain, or any patient with altered mental status.[70] Several other screening tools exist, including the Denver criteria and Memphis criteria, as well as a Denver grading system to predict stroke risk and mortality. Seat belt signs on the neck may suggest insidious vascular injury, but a review of 131 patients with a seat belt sign at the neck found that only 0.76% had a significant vascular injury.[71]

Delayed presentation of a vascular injury is most often neurologic in nature, with symptoms ranging from TIA to global cerebral ischemia. Horner's syndrome has been associated with vascular injury, particularly carotid artery dissection.[68] Seventeen to 35% of patients do not develop neurologic symptoms for more than 24 hours,[72] and delay in onset of neurologic sequelae of weeks to years has been reported. TIAs usually result from release of small emboli from the injured vessel, which can herald the onset of a profound deficit. Thus any focal neurologic abnormality discovered by history or examination should prompt the emergency physician to include vascular injuries in the differential diagnosis. Blunt cervical vascular injuries represent some of the most under-reported injuries because of their insidious presentation but ultimate association with a catastrophic neurologic outcome.

Diagnostic Strategies

Some centers routinely obtain contrast studies of all potentially significant neck wounds; others restrict imaging to zone I and zone III injuries. Zone I injuries in particular can harbor clinically occult arterial injuries, and routine preoperative imaging has been historically advocated to detect injury and facilitate a judicious surgical approach when positive. Likewise, zone III vascular injuries can be exceedingly difficult to approach surgically, and thus some surgeons still prefer preoperative imaging followed by exploration for any positive or equivocal findings. Many surgeons believe that pre-exploratory vascular studies are noncontributory in zone II injuries and may lead to delays in definitive care because these lesions are easily approached surgically.

With the advent of newer-generation machines, CT-A (64-slice or more CT angiography) has largely replaced conventional angiography. Part of the attraction is that it is rapid, readily available, and accurate.[73-75] CT-A allows for the detection of many types of vascular injuries, and it characterizes cervical soft tissues, cervical vertebrae, and spinal cord as well as aerodigestive structures. Increasingly more centers rely on CT-A when no clear surgical indications are apparent, although CT-A can potentially miss lethal lesions, such as pseudoaneurysms. Centers that prefer a selective approach are increasingly reporting success with this modality in the face of platysma violation.[76] CT-A for the diagnosis of vascular injury in penetrating trauma has been shown to have a sensitivity and specificity of 90 to 100% and 99 to 100%.[77-80] For victims of blunt trauma, the sensitivity of CT-A may be substantially lower, 47 to 74%, possibly because of the nature of the injuries as well as the fact that many of the data come from images obtained on single-slice scanners,[69,81-83] Three studies using newer generation technology found a sensitivity close to 100% when compared with digital subtraction angiography or long-term clinical outcome.[84-86] One systematic review found a pooled sensitivity of 76.8% and negative predictive value of 89.9% across the existing literature.[87] It seems likely that CT-A is a reasonable diagnostic choice if performed in a 16-slice or greater scanner.[88] As some of these patients have focal or hemispheric neurologic findings that prompt head CT, performance of CT-A immediately afterward streamlines the workup, especially considering that ischemic changes may be initially occult on the head CT.

Historically, conventional arteriography has been used extensively to detect vascular injury in patients with both blunt and penetrating injuries. Four-vessel arteriography is time-consuming and expensive but historically felt to be helpful in planning the best surgical approach. If ordered, this contrast study should include the intracranial portion of the carotid artery with zone III injuries or suspected blunt cervical trauma. Zone I injuries should include the aortic arch with its branches. Despite a sensitivity and specificity of nearly 100% and a complication rate of less than 2% for arteriography, other, less invasive diagnostic tests, such as CT-A, have been suggested because of their accuracy, speed, cost, and efficacy.[89]

Duplex ultrasonography has been used in combination with or instead of arteriography to exclude cervical vascular injury in patients with both penetrating and blunt trauma. Despite clinical success, limitations of ultrasonography include the risk of missing zone I and zone III injuries and the lack of 24-hour availability at many centers. For penetrating injury, carotid duplex Doppler has been shown to diagnose vascular injuries with a sensitivity of 91 to 95%, with higher accuracy in more clinically important injuries.[35,90] For all symptomatic dissection patients without obvious evidence of stroke, sensitivity of ultrasound is 70% for carotid and 75 to 86% for vertebral arteries,[91,92] though rates as low as 38.5% were found in one study.[77] Much of the lost sensitivity in the imaging of the carotid artery is a result of poor visualization of the distal third of the vessel.[65]

Magnetic resonance angiography (MRA) has also been reported to be helpful despite high cost and potential lack of 24-hour availability. MRA has additional distinct disadvantages that include remote location in many centers, the contraindication of metallic foreign bodies (bullet fragments), and the inability to directly visualize the neck during the procedure for expanding hematoma. Its sensitivity is likely equivalent to that of CT-A, and possibly inferior for vertebral dissections.[93] Although not indicated in most cases of suspected vascular injury, plain films can occasionally be useful. Anteroposterior and lateral neck films can help determine a bullet trajectory by allowing comparison of the entrance wound with the location of the foreign body, if present, though ricochet off a bone may render the estimated trajectory inaccurate. Chest radiographs allow evaluation of the mediastinum and identification of hemothorax or pneumothorax.

Management

Penetrating Injury. The ideal management strategy for injuries of the vascular system resulting from penetrating trauma has

www.ketabpezeshki.com 66485457-66963820

not been determined. Because many of these patients are young with anticipated "clean" carotid arteries, some surgeons routinely attempt surgical repair. Because of concern that reperfusion might convert an ischemic infarction to a hemorrhagic infarction in patients with profound neurologic deficit, others prefer ligation over repair in a select population of patients.

Blunt Injury. Treatment options for blunt artery injuries depend in part on the mechanism and type of injury and location of the lesion. Treatment modalities include surgery, anticoagulation, and observation. Recommendations are mixed as to whether antiplatelet therapy or anticoagulation is most appropriate to prevent clot propagation in arterial dissections.[94] Antiplatelet agents and heparin have comparable injury healing rates.[95] Because of high complication rates in trauma patients, treatment modalities should be initiated with appropriate consultation. Surgical treatment includes ligation, resection, thrombectomy, and endovascular stent placement. Delayed formation of pseudoaneurysms can be a complication of even low-grade injuries.

Venous Air Embolism. VAE is a subset of vascular injuries that can lead to life-threatening complications if not detected. VAE has been reported after blunt, penetrating, and iatrogenic mechanisms. VAE occurs when air enters the injured vessel, usually during inspiration, resulting in distal vascular occlusion and infarction. In any patient with a suspected major venous injury, direct pressure should be maintained over the wound while the patient is kept in Trendelenburg's position and left lateral decubitus position if injuries allow. Autopsy reports on such trauma victims reveal air in both the right side of the heart and the pulmonary artery. When standard treatment fails in a pulseless trauma patient, VAE should be immediately suspected and the right ventricle aspirated for air after the aorta has been cross-clamped. Rarely, air embolism has been reported with arterial injuries as well.[1]

Nervous System

When evaluating any patient with neck trauma, the examiner should remember that the brachial plexus, peripheral nerve roots, cervical sympathetic chain, and cranial nerves VII, IX, X, XI, and XII are vulnerable, as well as the spinal cord. Neurologic deficit can also result from vascular injury with subsequent cerebral ischemia. Complete cord injury can result in spinal (neurogenic) shock with paraplegia, bradycardia, and hypotension. Brown-Séquard syndrome (hemisection of the spinal cord) arises with ipsilateral hemiplegia and contralateral sensory deficit. Cervical spine fractures and cord injuries are most commonly found in GSWs (1.35% and 0.94%, respectively), followed by direct blunt trauma. Either injury is rare from SWs (0.12% and 0.11%).[96] Brachial plexus, spinal root, and peripheral nerve injuries have been reported after neck trauma and can result in both sensory and motor deficits. Phrenic nerve injury may compromise spontaneous respiration by causing ipsilateral diaphragmatic paralysis. Hoarseness can result from direct laryngeal trauma, but injury to the recurrent laryngeal nerve, which branches off the vagus nerve (cranial nerve X), should also be suspected, with vocal cord paralysis on the affected side.

Thoracic Duct, Glandular, and Retropharyngeal Injuries

Other, less common injuries have been reported in association with neck trauma with variable signs and symptoms. Thoracic duct injuries are less likely to be apparent initially and are frequently diagnosed intraoperatively or after development of a chylothorax. Glandular wounds, including those of the thyroid, parathyroid, and salivary glands, are reported rarely. Retropharyngeal hematomas are also extremely rare but can result in life-threatening airway compromise.[1,97]

Near Hanging and Strangulation

Epidemiology

Hanging and strangulation represent the second most common form of suicide in the United States after firearm use.[98] Approximately 9000 strangulation deaths occur annually in the United States.[99]

The terms *hanging* and *strangulation* are often used interchangeably, with hanging being a subset of strangulation. Hanging is categorized as judicial (complete hanging) or nonjudicial (incomplete hanging). *Complete hanging* refers to the presence of a ligature around the victim's neck and a subsequent drop resulting in the victim being freely suspended. In contrast, *incomplete hanging* refers to the partial suspension of the victim's body with some part still in contact with the ground. Judicial hanging victims classically fall at least the height of their body, whereas incomplete hanging is more likely to be seen in confined spaces (e.g., homes and jail cells), where a fall from height resulting in full body suspension is less possible. On the basis of the location of the ligature knot, hanging is further divided into atypical and typical categories. *Typical hanging* refers to the knot being midline directly under the occiput, which leads to a higher likelihood of complete arterial occlusion. *Atypical hanging* refers to all other knot placements.[100]

Manual strangulation and *ligature strangulation* refer to external compression of the neck, usually by hands or ligature, but independent of the weight of the victim.[101] *Postural strangulation,* generally seen in the younger pediatric population, refers to death sustained by the victim's body weight compressing the anterior neck against a firm object.

Pathophysiology

Judicial hanging with adequate fall distance results in forceful distraction of the head from the neck and body. This leads to high cervical fractures, such as the classic hangman's fracture (fracture through both pedicles of C2), complete cord transection, and death. Attempted-suicide hangings frequently occur at inadequate height and therefore tend to mimic nonjudicial strangulation. In essentially all types of nonjudicial strangulation, the ligature or external force initially applied causes venous congestion with stasis of cerebral blood flow leading to unconsciousness. Once the person is limp, the ligature or external force can tighten further, leading to complete arterial occlusion and ultimately to brain injury or death. Vagal reflexes resulting from pressure on the carotid body may contribute to fatal dysrhythmias, as may increased sympathetic tone from pericarotid sinus pressure. Compression of the airway does not play as significant a role in incomplete hanging as vascular occlusion.[100]

Pulmonary sequelae are frequently seen in near-hanging victims and include pulmonary edema, bronchopneumonia, and acute respiratory distress syndrome (ARDS).[100] These complications are responsible for most in-hospital deaths after near hanging. Pulmonary edema occurs from one of two mechanisms. *Neurogenic* pulmonary edema results from centrally mediated, massive sympathetic discharge. Because it is more often seen in association with serious brain injury, neurogenic pulmonary edema has poor prognostic implications. *Postobstructive* pulmonary edema is generally associated with a better neurologic outcome. It is initiated by marked negative intrapleural pressure, which is generated by forceful inspiratory effort against an extrathoracic obstruction.

www.ketabpezeshki.com 66485457-66963820

When the obstruction is removed, the onset of pulmonary edema can be rapid and can lead to ARDS.[100]

Clinical Features

External trauma may or may not be evident, depending on the mechanism of injury. If present, ligature marks appear as indentations around the neck, ranging from mild erythema to leather-like grooves following the course of the ligature. Fingernail scratches, abrasions, and contusions are variably present on the external neck as well. *Tardieu's spots* are highly correlated with asphyxial deaths; these petechial hemorrhages are seen in the conjunctiva, mucous membranes, and skin cephalad to the ligature marks. They occur when the venous pressure rises in response to ligature tightening. Laryngeal injuries are reported in near-hanging victims. Thyroid cartilage fractures are seen in approximately 50% of all nonjudicial hanging deaths, and hyoid bone fractures occur in 20%. Cricoid cartilage fractures are rarely reported and typically occur with manual strangulation.[100] Resulting laryngeal fractures are rarely clinically significant in survivors, and standard airway techniques are recommended.

Vascular injury leading to delayed neurologic sequelae after near hanging is rare, but reported, and is more frequent in fatal cases.[102] It most often results from carotid intimal dissection or thrombus formation, resulting in partial or complete vascular occlusion or embolism.[103] Carotid vascular studies should be considered in patients with unexplained focal or global neurologic deficits. Cervical spine fractures, subluxations, and cord injury are uncommon in nonjudicial near hangings but have been reported.[104,105] Although not reported, phrenic nerve injury and resultant diaphragmatic paralysis is a theoretic possibility as well.[106]

Management

Suggested radiographic workup includes head CT and neck CT-A.[105] Ventilatory support is indicated for maintenance of adequate oxygenation and ventilation in the comatose patient. The addition of positive end-expiratory pressure is often necessary, especially when pulmonary edema or ARDS develops.[73] Aggressive resuscitation is warranted in the unconscious patient; the initial Glasgow Coma Scale score is generally not predictive of outcome.[105,107] The altered or comatose patient should be assumed to have cerebral edema with elevated intracranial pressure, and cerebral resuscitation measures are actively initiated with use of standard technique.

Definitive studies providing guidelines for the management of hypoxic brain injury specifically related to near-hanging or strangulation injuries are lacking. Several small recent series indicate a potential role for induced mild hypothermia in comatose survivors of strangulation.[108-110]

KEY CONCEPTS

- Neck trauma results from one of three major mechanisms: blunt injury, penetrating injury, or near hanging or strangulation.
- The leading cause of immediate death after neck trauma is exsanguination secondary to vascular injury.
- The leading cause of delayed death after neck trauma is esophageal injury. These wounds are rare, frequently insidious, and associated with high mortality rates if missed.
- Neck wounds should never be probed through the platysma muscle because massive hemorrhage or air embolus can ensue.
- Cervical collars can obscure impending airway disasters (e.g., expanding hematomas) and other signs suggestive of injury if not removed periodically to allow serial examinations.
- Unless a contraindication exists, orotracheal rapid sequence intubation is safe and effective in the hands of an experienced intubator.
- Vascular injuries resulting from blunt trauma represent some of the most under-reported injuries because of their propensity for delayed neurologic sequelae.
- There is ongoing debate regarding whether physical examination is sensitive at detecting visceral or vascular injury, and the role of CT-A is increasing.
- Suspicion of venous air embolism should prompt direct wound pressure, occlusive dressings, Trendelenburg's position, and, if the patient is in cardiopulmonary arrest, aspiration of air from the right side of the heart.
- Transcervical gunshot wounds are a subset of injuries with a twofold-increased incidence of visceral-vascular injuries compared with injuries that do not cross the midline.
- All near-hanging or strangulation patients who are comatose or have altered consciousness may have elevated intracranial pressure, and appropriate cerebral resuscitation measures should be initiated.
- The leading cause of in-hospital death in victims of near hanging or strangulation is pulmonary complications (pneumonia, pulmonary edema, and ARDS).

CHAPTER 45

THORACIC TRAUMA

Marc Eckstein and Sean O. Henderson

EPIDEMIOLOGY

Thoracic injury directly accounts for 20 to 25% of deaths from trauma, resulting in more than 16,000 deaths annually in the United States. The most common cause of injuries leading to accidental death in the United States is motor vehicle collisions (MVCs) in which immediate deaths are often caused by rupture of the myocardial wall or the thoracic aorta. Early deaths (within the first 30 minutes to 3 hours) resulting from thoracic trauma are often preventable. Causes of these include tension pneumothorax, cardiac tamponade, airway obstruction, and uncontrolled hemorrhage. Because these problems are often reversible or may be temporized nonoperatively, it is vital that emergency physicians be thoroughly familiar with their pathophysiology, clinical presentation, diagnosis, and treatment.[1]

Approximately 75% of patients with thoracic trauma can be managed expectantly with simple tube thoracostomy and volume resuscitation. Therefore initial care and disposition of these patients is usually performed by emergency physicians. Definitive care of these patients is often multidisciplinary in nature, involving trauma surgeons, cardiothoracic surgeons, and intensivists. Improvement in the understanding of the underlying physiologic mechanisms involved, the advancement of newer imaging modalities, minimally invasive approaches, and pharmacologic therapy contribute to decreasing the morbidity and mortality of these injured patients. The role of multidetector helical computed tomography (CT) scanning in the evaluation of trauma patients continues to expand. Although CT scans provide much greater diagnostic sensitivity than plain radiography, the precise indications for CT scanning in trauma patients remain unclear. Concerns regarding cost, contrast-induced nephrotoxicity, and cumulative radiation exposure to the thorax have been mounting.[2]

Injuries to the lung parenchyma are common in severely injured patients and include contusion, laceration, and hematoma.[1] Hemothorax and pneumothorax are also common injuries in patients with thoracic trauma. Treatment of these injuries has changed during the past decade primarily because of advances in diagnostic imaging techniques and an increased understanding of the pathophysiology.

CHEST WALL INJURY

Epidemiology

Among victims sustaining thoracic trauma, approximately 50% will have chest wall injury: 10% minor, 35% major, and 5% flail chest injuries.[1] Chest wall injuries are not always obvious and can easily be overlooked during the initial evaluation.

Anatomy and Pathophysiology

An intact chest wall is necessary for normal ventilation. Outward expansion of the thorax by the respiratory muscles with descent of the diaphragm creates negative intrathoracic pressure. This causes passive air entry into the lungs during inspiration. Chest trauma, particularly blunt trauma, can severely disturb the physiology of respiration. Fortunately, most individuals have substantial respiratory reserve and can tolerate significant chest wall injury with adequate support.

Clinical Features

Elderly patients or those with preexisting pulmonary disease are sometimes unable to compensate for even minor chest wall trauma and therefore require closer attention. It is important to completely disrobe the patient and observe the respiratory rate, adequacy of tidal volume, and respiratory effort. Many chest wall injuries may be detected only by careful palpation of the chest wall, noting any areas of deformity, tenderness, or crepitus.

RIB FRACTURE

Epidemiology

Simple rib fractures are the most common form of significant chest injury, accounting for more than half the cases of blunt trauma.[1] The susceptibility to rib fracture increases with age. The importance of this injury is not the fracture itself but rather the associated potential complications, particularly pneumothorax, hemothorax, pulmonary contusions, and post-traumatic pneumonia. Rib fractures in children signify serious trauma to the thorax and have a high incidence of underlying injury.

Anatomy and Pathophysiology

Ribs usually break at the point of impact or at the posterior angle or posterolateral area, which is structurally the weakest area. The fourth through ninth ribs are most commonly involved. Ribs 1 to 3 are relatively protected, and ribs 9 to 12 are more mobile at the anterior end. This confers the relative resistance to fracture of the "high" and "low" ribs. Fractures occur more commonly in adults than in children, and this is attributed to the relative inelasticity of the older chest wall compared with the more compliant chest wall in children.

The true danger of rib fracture involves not the rib itself but the potential for penetrating injury to the pleura, lung, liver, or spleen. Fractures of ribs 9 to 11 are associated with intra-abdominal

www.ketabpezeshki.com 66485457-66963820

injury. Patients with right-sided rib fractures are almost three times more likely to have a hepatic injury, and patients with left-sided rib fractures are almost four times more likely to have a splenic injury.[3] Fractures of ribs 1 to 3 may indicate severe intrathoracic injury. The presence of two or more rib fractures at any level is associated with a higher incidence of internal injuries. Elderly patients with multiple rib fractures have a greater incidence of pneumonia and a higher mortality compared with patients younger than age 65 years.[4-6] To prevent a minor injury from developing into a serious complication, these fractures should be diagnosed rapidly and treated expectantly.

Clinical Features

The diagnosis can be suspected clinically, with tenderness, bony crepitus, ecchymosis, and muscle spasm over the rib being the most common findings. Also, bimanual compression of the thoracic cage remote from the site of injury (barrel compression test) usually produces pain at the site of fracture.

Diagnostic Strategies

Although clinical impression and physical findings are sensitive, they are not specific and are therefore unreliable for making an accurate diagnosis. Chest x-ray films often do not demonstrate the presence of rib fractures but are of greatest value in suggesting significant intrathoracic and mediastinal injuries. Although the upright posteroanterior chest radiograph has a higher yield in detecting rib fractures or their complications compared with other views, CT scans are significantly more effective than chest x-ray examination in detecting rib fractures (Fig. 45-1).[7] Rib series and expiratory, oblique, and cone-down views should not be used routinely. However, if simple rib fractures are strongly suspected or recognized on a clinical basis, there is no need to routinely obtain a CT scan unless other intrathoracic pathology needs to be studied.

Nonetheless, x-ray studies are often ordered, even though 50% of single-rib fractures are not seen on the initial x-ray film. A CT scan should be considered based on the mechanism of injury, physical examination, hemodynamic and respiratory parameters, abnormal findings on chest x-ray examination (especially widened mediastinum), or clinical evidence of multiple rib fractures, especially of the lower ribs (which may herald a splenic or hepatic injury).

Figure 45-1. Multiple rib fractures seen on chest computed tomography scan. (Also note presence of bilateral hemothoraces.)

Management

Treatment of patients with acute rib fractures is based on adequate pain relief and the maintenance of pulmonary function. Oral pain medications are usually sufficient for young and healthy patients. Continuing daily activities and deep breathing should be stressed to ensure ventilation and prevent atelectasis. It is helpful to advise patients to take their pain medications and wait 30 to 45 minutes before performing deep breathing exercises, perhaps with an incentive spirometer. Pain relief should be effective or patients will not maintain activity. Binders, belts, and other restrictive devices should not be used because although they can decrease pain, they also promote hypoventilation with subsequent atelectasis and pneumonia.

The greater the number of fractured ribs, the higher the mortality and morbidity rates. Patients with three or more fractured ribs, despite the lack of other traumatic injuries, should likely be hospitalized to receive aggressive pulmonary therapy and appropriate effective analgesia. Elderly patients with six or more fractured ribs should be treated in intensive care units owing to high morbidity and mortality. Older patients will probably require narcotic preparations, but care should be taken to avoid oversedation because of the potential for respiratory failure.[8]

Multiple rib fractures in trauma patients are associated with significant morbidity and mortality. Intercostal nerve blocks with a long-acting anesthetic such as bupivacaine with epinephrine may relieve symptoms up to 12 hours with excellent results. Such nerve blocks are achieved by administration of 1 or 2% lidocaine or 0.25% bupivacaine along the inferior rib margin several centimeters posterior to the site of the fracture. One rib above and one rib below the fractured rib should also be blocked for optimal analgesia. Other alternatives for hospitalized patients include patient-controlled analgesia, parenteral opiates, and thoracic epidural analgesia.[9]

Clinical Course

Most rib fractures heal uneventfully within 3 to 6 weeks, and patients should expect a gradual decrease in their discomfort during this period. Analgesics are usually necessary during the first 1 or 2 weeks. However, in addition to the complications of hemopneumothorax, atelectasis, pulmonary contusion, and pneumonia, rib fractures can result in post-traumatic neuroma or costochondral separation. These unusual complications are painful and heal slowly. Special attention should be paid to patients with displaced rib fractures, who may develop delayed hemorrhage resulting in death, typically from intercostal artery tears that clot off and then rebleed.[10] In these patients, admission and close observation for these delayed sequelae are typically warranted.

STERNAL FRACTURE

Epidemiology

Sternal fractures and dislocations are caused primarily by anterior blunt chest trauma, usually from MVCs when the chest strikes the steering wheel. Risk factors for sternal fracture from blunt trauma include types of vehicular passenger restraint systems and patient age. Restrained passengers are more likely than unrestrained passengers to sustain sternal fracture. In fact, the rate of occurrence of sternal fractures has increased threefold since the use of across-the-shoulder seat belts became widespread.

Anatomy and Pathophysiology

Sternal fracture usually results from the diagonal strap of a seat belt restraining the upper part of the sternum. During rapid

www.ketabpezeshki.com 66485457-66963820

deceleration from a frontal impact, the forward thrust of the body against the fixed seat belt across the sternum results in a fracture at that location. The location of the sternal fracture varies depending on the position of the belt, patient size, the magnitude of the impact, and the vector of the forces.

Similarly, depending on patient age, the likelihood of sternal fracture is variable. In general, sternal fractures are more common in older patients than in younger patients, and they are slightly more common in women than in men. It is believed that the more elastic and pliable chest wall of younger people allows more efficient transmission of kinetic energy to the underlying mediastinum. Although skeletal injury is less likely to occur in younger patients, damage to soft tissue structures underneath is greater. In older patients, the energy of impact is dissipated in the sternum, resulting in fewer intrathoracic injuries but a higher frequency of sternal fractures. Multiple rib fractures and lung contusion are concomitant injuries in more than 10% of diagnosed sternal fractures.

The natural history of a nondisplaced sternal fracture is contrary to intuition. It had been thought that the magnitude of the forces required to fracture the sternum must be associated with significant trauma to the mediastinal structures. However, isolated sternal fractures are relatively benign, with low mortality (<1%) and low intrathoracic morbidity.[11]

Cardiac complications, such as myocardial contusion, occur in 1.5 to 6% of cases. There is no association between sternal fracture and aortic rupture. Spinal fractures are seen in less than 10% of cases and rib fractures in 21%.[12] Although sternal fractures may occur in the context of major blunt chest trauma, the presence of a sternal fracture does not imply other major life-threatening conditions. However, associated mediastinal injuries should be considered.

Mediastinal hematomas, whether or not they are related to aortic injuries, can be life-threatening. The dual problem of acute blood loss and sudden alterations in cardiopulmonary physiology can result in hemodynamic deterioration. In addition to circulatory collapse from exsanguination, mediastinal hematomas can cause death from compression of adjacent structures.

Clinical Features

Sternal fractures typically cause anterior chest pain, point tenderness over the sternum, ecchymosis, soft tissue swelling, or palpable deformity. These findings together with the history can often lead to the diagnosis.

Diagnostic Strategies

Most sternal fractures are transverse, and a lateral radiographic view is often diagnostic. These fractures can be missed radiographically because a lateral plain chest x-ray film is not usually obtained during the initial trauma evaluation. Furthermore, plain films are sometimes inconclusive. Even if the sternal fracture is diagnosed by plain radiographs, the extent of the injury is often underappreciated. The advent of helical CT, especially with three-dimensional images of the skeletal system, has resulted in markedly improved diagnosis of sternal fractures. Emerging literature suggests that ultrasound (US) may be more sensitive than plain radiography.[13]

Although most nondisplaced sternal fractures are not associated with significant intrathoracic injuries, a conservative approach is to obtain a chest CT scan to rule out any other pathology. This may be clinically important in determining the best management of the sternal fracture in terms of conservative management versus surgical fixation.[14] Chest CT also helps to rule out any associated mediastinal injuries. A 12-lead electrocardiogram (ECG) should also be obtained during the initial evaluation.

Management

Treatment consists of providing adequate analgesia. In the absence of associated injuries, more than 95% of patients with isolated sternal fractures who can achieve adequate pain control with oral medications can be safely discharged home. However, a small subset of patients have sternal fractures that are displaced or produce overlying bone fragments that may cause severe pain, respiratory compromise, or physical deformity and, if untreated mechanically, result in nonunion. These patients are best referred for operative fixation.[15]

COSTOCHONDRAL SEPARATION

Costochondral separation may also be caused by blunt anterior chest trauma. The signs and symptoms are similar to those of rib fracture, but because of the poor vascularity of healing cartilage, pain may persist for many weeks. The chest x-ray film is usually normal, but there is a snapping sensation with deep respiration. Outpatient management of these patients is similar to that of patients with rib fractures. Flail chest can also occur from massive costochondral separation at one or multiple points, but this is uncommon.

FLAIL CHEST

Epidemiology

Flail chest is a fairly uncommon injury that is most often accompanied by a significant underlying pulmonary parenchymal injury and can be a life-threatening thoracic injury. Its management is often complicated by the other injuries with which it is frequently associated.

Anatomy and Pathophysiology

Flail chest results when three or more adjacent ribs are fractured at two points, allowing a freely moving segment of the chest wall to move in paradoxical motion (Fig. 45-2). It can also occur with costochondral separation or vertical sternal fracture in combination with rib fractures. Because of its common association with pulmonary contusion, it is one of the most serious chest wall injuries (Fig. 45-3).

The physiology of respiration is adversely affected by flail chest in a number of ways. The paradoxical motion of the chest wall is

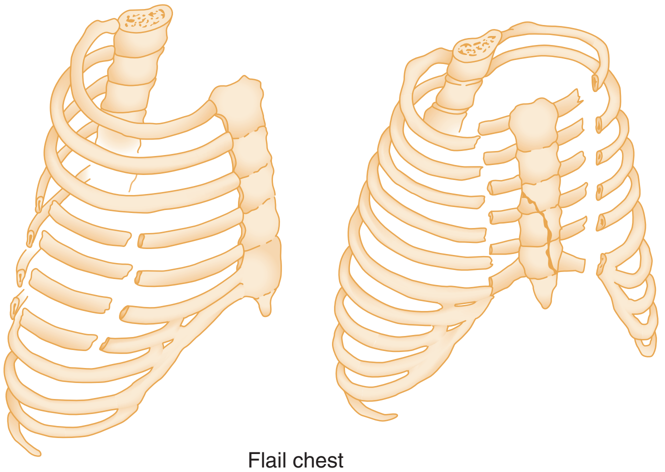

Figure 45-2. Flail chest. Fracture of several adjacent ribs in two places with lateral flail or central flail segments.

www.ketabpezeshki.com 66485457-66963820

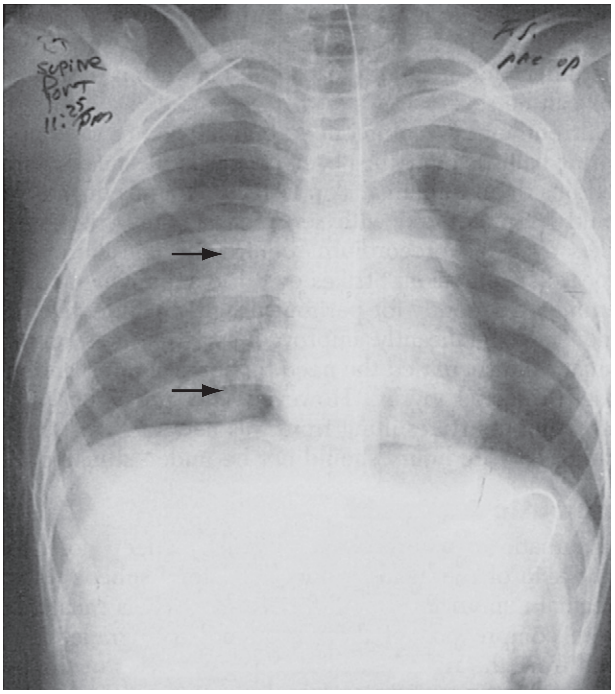

Figure 45-3. Bilateral alveolar infiltrates (*arrows*) suggesting pulmonary contusion. Pneumopericardium and pneumomediastinum are also present.

the hallmark of this condition, with the flail segment moving inward with inspiration and outward with expiration. Underlying pulmonary contusion is considered to be the major cause of respiratory insufficiency with flail chest. In addition, the pain of the injury causes muscular splinting with resultant atelectasis, hypoxemia, and decreased cardiac output.

Clinical Features

Flail chest is usually diagnosed by physical examination. This requires exposure of the patient's thorax and examination of the chest wall for paradoxical motion. Pain, tenderness, and crepitus can direct the examiner. In addition, the flail segment can sometimes be visualized to move separately and in an opposite direction from the rest of the thoracic cage during the respiratory cycle. Endotracheal intubation and positive-pressure ventilation will internally splint the chest wall, making the flail segment difficult to detect on physical examination.

Diagnostic Strategies

Multiple rib fractures can usually be identified on chest x-ray films. CT scan is much more accurate than plain films in detecting the presence and extent of underlying injury and contusion to the lung parenchyma. It is used routinely in some centers for all patients with major chest trauma.

Management

Out-of-hospital or emergency department (ED) stabilization of the flail segment by positioning the person with the injured side down or placing a sandbag on the affected segments has been abandoned. These interventions actually inhibit expansion of the chest and increase atelectasis of the injured lung. Oxygen should be administered, cardiac and oximetry monitors applied if available, and the patient observed for signs of an associated injury such as tension pneumothorax. A 12-lead ECG and cardiac enzymes should be obtained, with consideration given to obtaining an echocardiogram for significant dysrhythmias, high-grade blocks, or hemodynamic instability unexplained by other causes such as hemorrhage.

The outcome of flail chest injury is a function of associated injuries. Because many different physiologic mechanisms have been implicated in flail chest, there is no consensus about hospital treatment. The cornerstones of therapy include aggressive pulmonary physiotherapy, effective analgesia, selective use of endotracheal intubation and mechanical ventilation, and close observation for respiratory compromise.

Respiratory decompensation is the primary indication for endotracheal intubation and mechanical ventilation for patients with flail chest. Obvious problems, such as hemopneumothorax or severe pain, should be corrected before intubation and ventilation are presumed necessary. In fact, in the awake and cooperative patient, noninvasive continuous positive airway pressure (CPAP) by mask may obviate the need for intubation.[16] In general, the most conservative methods for maintaining adequate oxygenation and preventing complications should be used. Adequate analgesia is of paramount importance in patient recovery and may contribute to the return of normal respiratory mechanics.

Patients without respiratory compromise generally do well without ventilatory assistance. Several studies have found that patients treated with intercostal nerve blocks or high segmental epidural analgesia, oxygen, intensive chest physiotherapy, careful fluid management, and CPAP, with intubation reserved for patients in whom this therapy fails, have shorter hospital courses, fewer complications, and lower mortality rates.[17] Avoidance of endotracheal intubation, particularly prolonged intubation, is important in preventing pulmonary morbidity because intubation increases the risk of pneumonia.[18]

There is also evidence that early operative internal fixation of the flail segment results in a speedier recovery, decreased complications, and better cosmetic and functional results, and that it is cost-effective. Indications for open fixation for flail chest include patients who are unable to be weaned from the ventilator secondary to the mechanics of flail chest, persistent pain, severe chest wall instability, and a progressive decline in pulmonary functions.[15,19]

The patient with flail chest should be treated in the ED as if pulmonary contusion exists regardless of whether mechanical ventilation is used. The mortality rate associated with flail chest is between 8 and 35% and is directly related to the underlying and associated injuries. However, unilateral flail chest was reported to be infrequently associated with death in one large series.[20] Those who recover from flail chest may develop long-term disability with dyspnea, chronic thoracic pain, and exercise intolerance.

NONPENETRATING BALLISTIC INJURY

Epidemiology

Many law enforcement officers, emergency medical services personnel, and private security guards wear lightweight synthetic body armor for protection against gunshot injury. In addition, there have been a number of reports of armed robbers wearing such vests in anticipation of exchanging gunfire with police or security personnel.[21] These vests are "bullet resistant" rather than "bulletproof," depending on the weapon being used against them. They are composed of many different combinations of synthetic fibers such as Kevlar.

Another type of nonpenetrating ballistic injury is caused by rubber bullets and beanbag shotgun shells. Rubber bullets have been used for many years by police agencies throughout the world

www.ketabpezeshki.com 66485457-66963820

for crowd dispersal and for nonlethal use of force. Beanbag shotgun shells are nylon bags filled with pellets, which are fired from a standard shotgun. Both of these projectiles have the potential to cause serious injury despite their classification of "nonmetal" or "less-than-lethal" use of force.[22]

Anatomy and Pathophysiology

Although bullet penetration is usually prevented, the heart, liver, spleen, lung, and spinal cord are vulnerable to nonpenetrating ballistic injury that may occur despite innocent-appearing skin lesions.

Bullet-resistant vests are usually capable of stopping penetration by the low-velocity missiles of most handguns, but the kinetic energy of the missile can be transmitted through the layers of protective cloth or armor and produce significant injury without penetration.

Clinical Features

Patients who have been shot with "less-than-lethal projectiles" or with standard bullets while wearing bullet-resistant vests usually have erythema, ecchymosis, and marked tenderness to palpation over the affected area. There may be a projectile, such as a beanbag, still located in the wound. The area of tenderness and surrounding structures should be carefully palpated to identify any subcutaneous emphysema, crepitus, or bony step-offs.

Diagnostic Strategies

Plain film radiography should be used to identify any retained foreign bodies and any fractures or cortical violation. Strong consideration should be given to CT scanning, based on the type of projectile, the clinical examination, and the degree of tenderness and location of the wounds, to look for retained foreign bodies or "occult" injuries, such as pneumothorax, hemothorax, or intraperitoneal penetration.

Management

It is recommended that all victims of nonpenetrating ballistic injury be observed closely, with overnight observation considered. This is particularly true for injuries over the abdomen, where serial examinations in coordination with CT scanning will help to detect internal injuries that may manifest in a delayed manner.[23] Use of protective body armor has resulted in significantly improved survival rates and has dramatically decreased the need for surgical intervention in those protected by it. In addition, "less-than-lethal" projectiles, such as rubber bullets and beanbag shotgun shells, offer law enforcement an alternative to conventional weapons that are considered "use of deadly force." However, the possibility of an underlying injury resulting from this form of nonpenetrating ballistic injury should not be underestimated.

TRAUMATIC ASPHYXIA

Anatomy and Pathophysiology

Traumatic asphyxia is a rare syndrome caused by a severe compression of the thorax by a very heavy object causing a marked increase in thoracic and superior vena caval pressure, resulting in retrograde flow of blood from the right side of the heart into the great veins of the head and neck. The vena cava and the large veins of the head and neck do not have valves and therefore allow the transmission of pressure to the capillaries of the head and neck, which become engorged with blood.

Clinical Features

Traumatic asphyxia is characterized by a deep violet color of the skin of the head and neck, bilateral subconjunctival hemorrhages, petechiae, and facial edema. Stagnation develops from capillary atony and dilation, and as the blood desaturates, purplish discoloration of the skin occurs.[24] Although the appearance of these patients can be quite dramatic, the condition is usually benign and self-limited if the heavy object was removed before any hypoxic complications such as anoxic encephalopathy occurred.[25]

Diagnostic Strategies

The clinical significance lies with the possibility of intrathoracic injury from the violent force necessary to produce traumatic asphyxia. Chest wall and pulmonary injuries are most common. If the patient's examination and chest x-ray film show worrisome features, CT scanning of the chest should be performed.

Disturbance of vision has been attributed both to retinal hemorrhage, which is generally a permanent injury, and to retinal edema, which may cause transient changes in vision. One third of these patients lose consciousness, usually at the time of injury. Intracranial hemorrhages are rare, probably because of the shock-absorbing ability of the venous sinuses, but CT scan of the head should be done in patients with neurologic complaints. Neurologic manifestations typically clear within 24 to 48 hours, and long-term sequelae are uncommon.[25]

PULMONARY INJURIES

Subcutaneous Emphysema

Anatomy and Pathophysiology

Subcutaneous emphysema in the presence of chest wall trauma usually indicates a more serious thoracic injury. Although the presence of air in the tissues is a benign condition, in the context of chest trauma it usually represents serious injury to any air-containing structure within the thorax. Air enters the tissues either extrapleurally or intrapleurally. Extrapleural tears in the tracheobronchial tree allow air to leak into the mediastinum and soft tissues of the anterior neck, producing a pneumomediastinum, which rarely may progress to a tension pneumomediastinum. This most often occurs in patients who are undergoing positive-pressure ventilation and have a pneumopericardium visible on chest x-ray examination. They may also have Hamman's crunch, which is a crackling sound with each heartbeat, heard on cardiac auscultation. Intrapleural lesions, however, usually produce a pneumothorax by allowing air to escape the lung through the visceral pleura into the pleural space and then through the parietal pleura into the thoracic wall.

An esophageal tear resulting from Boerhaave's syndrome or penetrating injury may also produce a pneumomediastinum manifested by subcutaneous emphysema over the supraclavicular area and anterior neck. An additional cause of subcutaneous emphysema, which may or may not be indicative of intrathoracic injury, is found immediately adjacent to a penetrating wound of the thorax. A small amount of air may be introduced into the adjacent subcutaneous tissues from the outside at the time of penetration. However, it is assumed that this is secondary to a pneumothorax or pneumomediastinum, and appropriate diagnostic and therapeutic maneuvers to rule out or treat the intrathoracic injury should be carried out.

The presence of localized subcutaneous emphysema over the chest wall in the presence of blunt trauma is usually indicative of the presence of a traumatic pneumothorax, whereas the presence

www.ketabpezeshki.com 66485457-66963820

of subcutaneous emphysema over the supraclavicular area and anterior neck usually indicates a pneumomediastinum.

Management

Tension pneumothorax is considered and treated appropriately. If a tension pneumopericardium is suspected, then immediate pericardiocentesis with aspiration of air from the pericardial space may be lifesaving.

Although subcutaneous emphysema is a benign condition, massive accumulations can be uncomfortable to the patient. The underlying cause, such as pneumothorax, ruptured bronchus, or ruptured esophagus, is treated appropriately. Benign pneumomediastinum secondary to a Valsalva maneuver is treated with observation and high-flow oxygen to facilitate the reabsorption of nitrogen from tissues because the volume of nitrogen causes the discomfort.

Pulmonary Contusion

Epidemiology

Pulmonary contusion is reported to be present in 30 to 75% of patients with significant blunt chest trauma, most often from MVCs with rapid deceleration.[1] Pulmonary contusion can also be caused by high-velocity missile wounds and the high-energy shock waves of an explosion in air or water. Pulmonary contusion is the most common significant chest injury in children, and it is most commonly caused by an MVC or an automobile versus pedestrian accident.[21]

Anatomy and Pathophysiology

Pulmonary contusion is a direct bruise of the lung parenchyma followed by alveolar edema and hemorrhage but without an accompanying pulmonary laceration, as first described by Morgagni in 1761.[26]

The early diagnosis of pulmonary contusion is important if treatment is to be successful. The onset may be insidious, and therefore it should be suspected from the history of the mechanism of injury rather than the initial chest radiograph. Great force is required to produce pulmonary contusion, such as from a fall from height, an MVC, and other forms of significant trauma.

Clinical Features

The clinical manifestations include dyspnea, tachypnea, cyanosis, tachycardia, hypotension, and chest wall bruising. There are no specific signs for pulmonary contusion, but hemoptysis may be seen sometime during the patient's course, and moist rales or absent breath sounds may be heard on auscultation. Palpation of the chest wall commonly reveals fractured ribs. If flail chest is discovered, pulmonary contusion is commonly present.

Surprisingly, many of the worst contusions occur in patients without rib fractures. It has been theorized that the more elastic chest wall, as in younger individuals, transmits increased force to the thoracic contents. Although isolated pulmonary contusions can exist, they are associated with extrathoracic injuries in the majority of patients.[27]

Diagnostic Strategies

Care is taken not to focus exclusively on more dramatic injuries at the expense of failing to recognize the evolving pulmonary contusion. This is particularly true with the initial x-ray studies when overlying rib fracture, pneumothorax, aspiration pneumonitis, or poor radiograph quality may mask the contusion.

Figure 45-4. Chest computed tomography scan showing bilateral alveolar infiltrates suggesting pulmonary contusion. There are also multiple rib fractures and subcutaneous emphysema.

Typical radiographic findings begin to appear within minutes of injury and range from patchy, irregular, alveolar infiltrate to frank consolidation (Fig. 45-4). Usually, these changes are present on the initial examination, and they are almost always present within 6 hours. The rapidity of changes on chest x-ray visualization usually correlates with the severity of the contusion. Pulmonary contusion should be differentiated from acute respiratory distress syndrome (ARDS), with which it is often confused because the radiographic appearance of the two conditions may be similar. The contusion usually manifests within minutes of the initial injury, is usually localized to a segment or a lobe, is often apparent on the initial chest study, and tends to last 48 to 72 hours. ARDS is diffuse, and its development is usually delayed, with onset typically between 24 and 72 hours after injury.[28]

The increased frequency of CT scans for blunt trauma patients has resulted in a corresponding increase in the diagnosis of pulmonary contusion. CT scans have been shown to detect twice as many pulmonary contusions as plain radiographs.[7] Some authors suggest that pulmonary contusions visible only on CT scan and not on plain radiographs may not be clinically significant.[29]

Chest CT scan is particularly valuable to identify a pulmonary contusion in the acute phase after injury because plain chest x-ray films have a low sensitivity.[7] Although CT scan may not be necessary to make the diagnosis of a pulmonary contusion that is evident on plain chest radiography, it may be helpful to further define the extent of the contusion and to identify other thoracic injuries. Infectious complications, sternoclavicular joint dislocation, pneumothorax, misplaced endotracheal tube, intraperitoneal air, and vertebral fracture have all been identified by CT scan in the trauma patient. Occult pulmonary contusions are those that are visible only on CT scan, not plain radiographs, and usually involve more than 20% of the lung volume. These "occult" pulmonary contusions are not associated with a worse clinical outcome as compared with blunt trauma patients without pulmonary contusion.[29] Patients with pulmonary contusion visible on both conventional chest radiographs and the CT scan frequently have a higher contusion volume and a worse outcome than patients with occult pulmonary contusion. Thus pulmonary contusions that are visible on plain chest radiographs have a higher morbidity and mortality and should therefore receive special medical attention as compared with contusions only seen on the chest CT scan.

Arterial blood gases may be helpful in making the diagnosis of pulmonary contusion because most patients are hypoxemic at the time of admission. A low partial pressure of oxygen (Po_2) alone may be reason to suspect pulmonary contusion. A widening alveolar-arterial oxygen difference indicates a decreasing

www.ketabpezeshki.com 66485457-66963820

pulmonary diffusion capacity of the patient's contused lung, and it is one of the earliest and most accurate means of assessing the current status, progress, and prognosis.

Management

Treatment for pulmonary contusion is primarily supportive.[29] When only one lung has been severely contused and has caused significant hypoxemia, consideration should be given to intubating and ventilating each lung separately with a dual-lumen endotracheal tube and two ventilators. This allows for the difference in compliance between the injured and the normal lung and prevents hyperexpansion of one lung and gradual collapse of the other.[30] As with flail chest, however, intubation and mechanical ventilation should be avoided if possible because they are associated with an increase in morbidity, including pneumonia, sepsis, pneumothorax, hypercoagulability, and longer hospitalization.[31] The need for mechanical ventilation increases significantly when the area of pulmonary contusion exceeds 20% of total lung volume.[32]

Certain patients may benefit from a trial of noninvasive positive-pressure ventilation with BPAP or CPAP to avoid intubation and mechanical ventilation. In those patients most severely injured with extensive pulmonary contusions and the development of ARDS with severe hypoxia refractory to conventional therapy, some small studies suggest a possible role for extracorporeal membrane oxygenation.[33]

Certain procedures may ameliorate the pulmonary contusion, including the restriction of intravenous fluids to maintain intravascular volume within strict limits and aggressive supportive care consisting of vigorous tracheobronchial toilet, suctioning, and pain relief. These maneuvers may preclude the need for ventilator support and allow a more selective approach to flail chest and pulmonary contusion.

Another area of controversy in the management of pulmonary contusions is the appropriate use of crystalloid versus colloid solutions in resuscitation of the multiply injured patient with suspected contusion. Because of the potential for colloid sequestration within the pulmonary alveoli as a result of capillary leak, colloids are not recommended for use in treating these patients.

Pneumonia is the most common complication of pulmonary contusions, and it significantly worsens the prognosis. It develops insidiously, especially in patients treated with prophylactic antibiotics. Antibiotics should be reserved for use with specific organisms rather than given prophylactically.

Pulmonary Laceration

The lungs are most often lacerated from penetrating injury, but they may also be injured by the inward projection of a fractured rib or avulsion of a pleural adhesion. These injuries are usually minor and rarely life-threatening, and they can usually be treated with continuous oxygen therapy, observation, or tube thoracostomy. Severe lacerations are present in only 3% of patients with thoracic trauma, and they are usually associated with hemopneumothorax, multiple displaced rib fractures, and hemoptysis. Often, these life-threatening lacerations require thoracotomy with resection or tractotomy to control bleeding.

Pneumothorax

Epidemiology

Pneumothorax, which is the accumulation of air in the pleural space, is a common complication of chest trauma. It is reported to be present in 15 to 50% of patients who sustain significant chest trauma, and it is invariably present in those with transpleural penetrating injuries.[1]

Anatomy and Pathophysiology

Pneumothorax can be divided into three types depending on whether air has direct access to the pleural cavity: simple, communicating, and tension. A pneumothorax is considered simple (Fig. 45-5) when there is no communication with the atmosphere or any shift of the mediastinum or hemidiaphragm resulting from the accumulation of air. It can be graded according to the degree of collapse as visualized on the chest radiograph. A small pneumothorax occupies 15% or less of the pleural cavity, a moderate one 15 to 60%, and a large pneumothorax more than 60%. Traumatic pneumothorax is most often caused by a fractured rib that is driven inward, lacerating the pleura. It may also occur without a fracture when the impact is delivered at full inspiration with the glottis closed, leading to a tremendous increase in intra-alveolar pressure and the subsequent rupture of the alveoli. A penetrating injury, such as a gunshot or stab wound, may also produce a simple pneumothorax if there is no free communication with the atmosphere (Fig. 45-6).

Communicating Pneumothorax. A communicating pneumothorax (Fig. 45-7) is associated with a defect in the chest wall and most commonly occurs in combat injuries. In the civilian sector, this injury is typically secondary to shotgun wounds. Air can sometimes be heard flowing sonorously in and out of the defect, prompting the term "sucking chest wound." The loss of chest wall

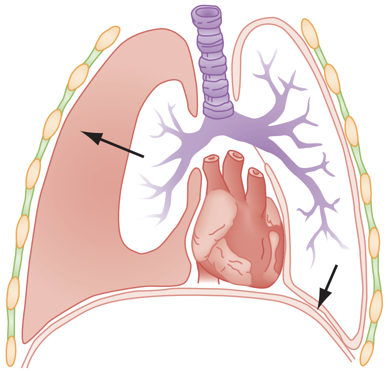

Figure 45-5. Closed pneumothorax. Simple pneumothorax is present in the right lung with air in the pleural cavity and collapse of the right lung.

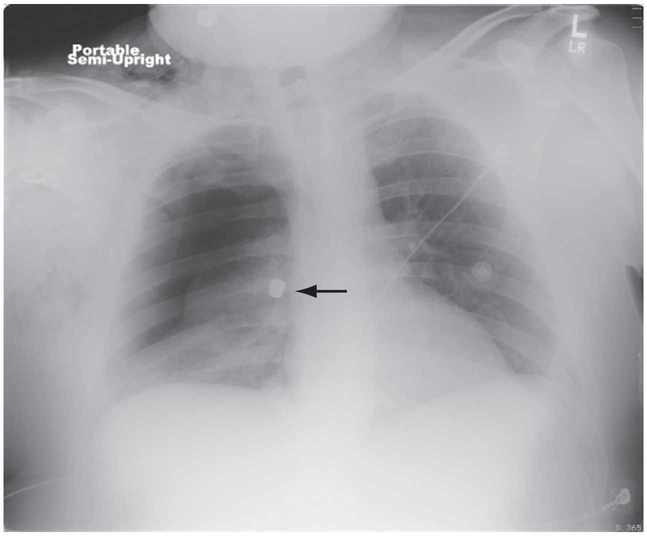

Figure 45-6. Chest radiograph showing a moderate-sized right pneumothorax. A bullet (*arrow*) can be seen near the right mediastinum.

www.ketabpezeshki.com 66485457-66963820

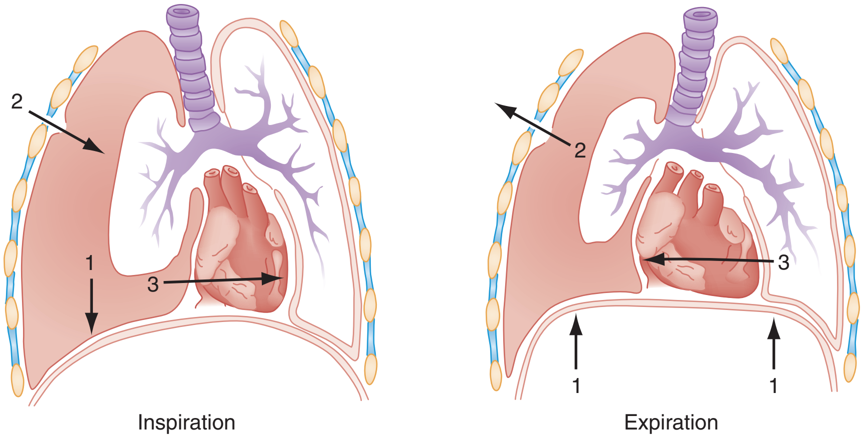

Figure 45-7. Inspiration: The diaphragm contracts causing negative intrathoracic pressure (*arrow 1*) that draws air through the sucking chest wound in the pleural cavity (*arrow 2*) and causing the mediastinal structures to shift to the patient's left (*arrow 3*). Expiration: the diaphragm recoils (*arrow 1*) causing air to exit the chest (*arrow 2*) and allowing the mediastium to shift back to normal position (*arrow 3*). The collapsed lung paradoxically shrinks on inspiration and expands on expiration.

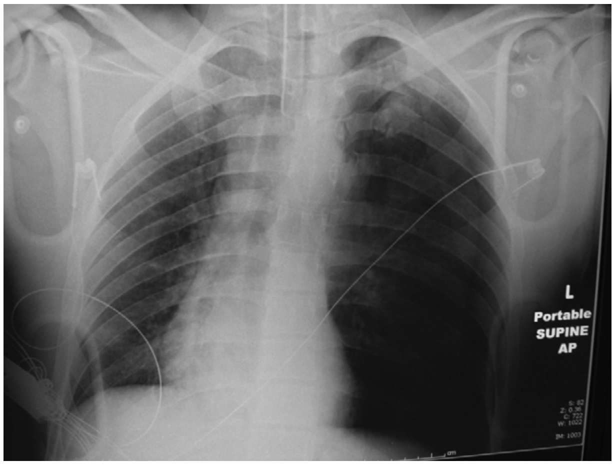

Figure 45-8. Tension pneumothorax seen in intubated patient.

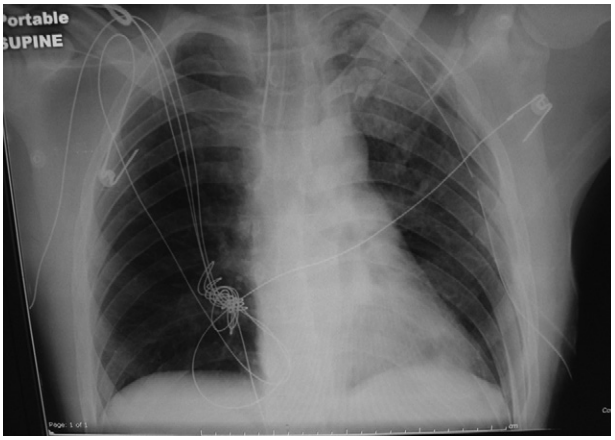

Figure 45-9. Resolution of the tension pneumothorax shown in Figure 45-7 with placement of a left-sided tube thoracostomy.

integrity causes the involved lung to paradoxically collapse on inspiration and expand slightly on expiration, forcing air in and out of the wound. This results in a large functional dead space for the normal lung and, together with the loss of ventilation of the involved lung, produces a severe ventilatory disturbance.

Tension Pneumothorax. The progressive accumulation of air under pressure within the pleural cavity, with shift of the mediastinum to the opposite hemithorax and compression of the contralateral lung and great vessels, is the constellations of findings in tension pneumothorax (Figs. 45-8 and 45-9). It occurs when the injury acts like a one-way valve, prevents free bilateral communication with the atmosphere, and leads to a progressive increase of intrapleural pressure. Air enters on inspiration but cannot exit with expiration. The resulting shift of mediastinal contents compresses the vena cava and distorts the cavoatrial junction, leading to decreased diastolic filling of the heart and subsequent decreased cardiac output. These changes result in the rapid onset of hypoxia, acidosis, and shock.

Clinical Features

Shortness of breath and chest pain are the most common presenting complaints of pneumothorax. The patient's appearance is highly variable, ranging from acutely ill with cyanosis and tachypnea to misleadingly healthy. The signs and symptoms are not always correlated with the degree of pneumothorax. The physical examination may reveal decreased or absent breath sounds and hyper-resonance over the involved side as well as subcutaneous emphysema, but small pneumothoraces may not be detectable on physical examination.

Patients with tension pneumothorax become acutely ill within minutes and develop severe cardiovascular and respiratory distress. They are dyspneic, agitated, restless, cyanotic, tachycardic, and hypotensive and display decreasing mental activity. The cardinal signs of tension pneumothorax are tachycardia, jugular venous distention (JVD), and absent breath sounds on the ipsilateral side. However, JVD may not reliably be present with massive blood loss. Hypotension will not occur as early as hypoxia and may represent a preterminal event.

Diagnostic Strategies

Because intrapleural air tends to collect at the apex of the lung, the initial chest radiograph should be an upright full inspiratory film if the patient's condition permits. An upright film will often reveal small pleural effusions that are not visible on supine films, and it also allows better visualization of the mediastinum. Although the chest radiograph has traditionally been the preferred initial study for diagnosing a simple pneumothorax, emerging literature suggests that a simple pneumothorax can be identified during the initial US examination of the trauma patient as part of the extended focused assessment with sonography in trauma (E-FAST)

www.ketabpezeshki.com 66485457-66963820

examination. Because FAST is becoming part of the routine initial evaluation of trauma patients, evaluation for the presence of a pneumothorax should be included in this rapid bedside examination, especially because this is performed before chest radiography. In fact, several studies have found that the US has greater sensitivity for pneumothorax than chest radiography.[34-36]

If a pneumothorax is suspected but not visualized on the initial inspiratory film, an expiratory film should be obtained because it makes the pneumothorax more apparent by reducing the lung volume. Notably, as many as one third of initial chest x-ray films will not detect a pneumothorax in trauma patients.[7] Although it is not recommended as a primary method of diagnosing pneumothorax, CT is very sensitive in finding small pneumothoraces even in supine patients. When CT scans are obtained to evaluate the abdomen, it may be helpful to take a few low cuts into the chest to exclude the presence of a small pneumothorax.

Occult Pneumothorax

A pneumothorax that is absent on the initial chest radiograph but is identified on subsequent chest or abdominal CT is called an *occult pneumothorax*. Occult pneumothorax is being diagnosed more frequently given the increased use of CT.[37,38] Studies have found rates as high as 75% for diagnosis on CT scan of occult pneumothorax that was absent on initial chest radiographs (Fig. 45-10).[7,37-39]

The diagnosis and treatment of tension pneumothorax should not be delayed. Although tension pneumothorax usually occurs dramatically, the clinical diagnosis is occasionally obscure, and chest x-ray examination may be required to suggest the diagnosis, particularly in patients on mechanical ventilation. This film will show complete lung collapse and shift of the mediastinum to the opposite side. Ideally, the diagnosis and treatment should be completed without a chest x-ray examination because the delay in obtaining this radiograph may adversely affect patient outcome. As previously stated, tension pneumothorax will typically cause significant hemodynamic compromise and therefore remains a clinical diagnosis.

Management

In the setting of penetrating trauma in which the patient is asymptomatic and the initial chest x-ray study is negative, the patient can be safely observed and the x-ray examination repeated. Previously, it was thought that if the patient was still asymptomatic and the radiograph negative after 6 hours, the patient could be discharged. Recent experience indicates that 3 hours is probably effective and safe for observation, with repeat x-ray film before discharge for patients with penetrating trauma.[40] Patients with blunt trauma in whom clinical suspicion for pneumothorax is high should still undergo a 6-hour delayed chest x-ray examination before discharge. However, if the stable patient undergoes initial screening chest CT that is negative for pneumothorax or hemothorax, the literature suggests that obtaining a delayed chest x-ray film is unnecessary, and these patients may be discharged from the ED.[41]

Simple Pneumothorax. Treatment of a simple pneumothorax depends on its cause and size. Most advocate treating a traumatic pneumothorax with a chest tube to correct any respiratory compromise; treatment with a chest tube is generally thought to be safer than observation in these patients. Small pneumothoraces (i.e., <15%), whether spontaneous or traumatic, have been treated with hospitalization and careful observation if the patient is otherwise healthy and symptom free, if the patient does not need anesthesia or positive-pressure ventilation, and the pneumothorax is not increasing in size.

Isolated apical pneumothoraces of less than 25% may be observed in patients with stab wounds. This conservative method seldom has application in multisystem trauma, and a chest tube should be inserted immediately on any signs of deterioration. Some suggest that because it is small and lacks symptoms, occult traumatic pneumothorax found only on CT scan can be managed with observation and does not need treatment. Studies indicate that these injuries can be handled as small but initially detectable pneumothoraces, with observation in hemodynamically stable patients without symptoms. The data regarding the frequency with which patients with occult pneumothorax on mechanical ventilation will require tube thoracostomy are conflicting.[42-44] However, an occult pneumothorax may be observed in a stable patient even if he or she is placed on positive-pressure ventilation.[44]

Any moderate to large pneumothorax should be treated with a chest tube. The indications for tube thoracostomy (chest tube) are listed in Box 45-1. The preferred site for insertion is the fourth or fifth intercostal space at the midaxillary line. If the tube is positioned posteriorly and directed toward the apex, it can effectively remove both air and fluid. This lateral placement of the tube is preferred not only because it is more efficient but also because it does not produce an easily visible cosmetic defect, as does the anterior site at the second interspace at the midclavicular line. With multisystem trauma, an adequate size chest tube (36-F to 40-F in adults and 16-F to 32-F in children) should be used,

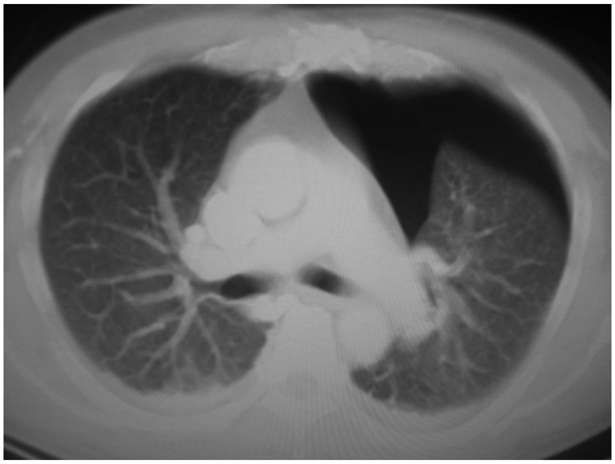

Figure 45-10. Occult pneumothorax. Large left-sided pneumothorax visible on chest computed tomography scan, which was not visible on chest x-ray film.

Box 45-1 Indications for Tube Thoracostomy

- Traumatic cause of pneumothorax (except asymptomatic, apical pneumothorax)
- Moderate to large pneumothorax
- Respiratory symptoms regardless of size of pneumothorax
- Increasing size of pneumothorax after initial conservative therapy
- Recurrence of pneumothorax after removal of the initial chest tube
- Patient requires ventilator support
- Patient requires general anesthesia
- Associated hemothorax
- Bilateral pneumothorax regardless of size
- Tension pneumothorax

particularly in cases of major trauma, when hemothorax is likely to occur.

Care is taken to be certain the vent holes along the side of the tube are all inside the chest cavity. A radiopaque line along the side of the tube with interruptions at these drainage holes helps greatly in radiographically interpreting tube position. The tube should be attached to a water seal drainage system that allows reexpansion of the pneumothorax. If there is significant air leak or a large hemothorax, the tube may be connected to a source of constant vacuum at 20 to 30 cm H_2O for more rapid reexpansion.

Tube thoracostomy does have some potentially serious complications, including the formation of a hemothorax, pulmonary edema, bronchopleural fistula, pleural leaks, empyema, subcutaneous emphysema, infection, intercostal artery laceration, contralateral pneumothorax, and parenchymal injury.[45-47] To reduce the incidence of empyema and pneumonitis, current recommendations include the administration of empirical antibiotics with all tube thoracostomy placements.[48] Pneumothoraces that have been present for more than 3 days should be reexpanded gradually without suction to avoid reexpansion pulmonary edema.

Communicating Pneumothorax. For a patient with a communicating pneumothorax in the out-of-hospital setting, the defect should be covered immediately, which helps convert the condition to a closed pneumothorax and eliminates the major physiologic abnormality. An occlusive dressing of petrolatum gauze can be applied, but care should be taken because this can convert the injury to a tension pneumothorax, especially in patients who are intubated and undergoing positive-pressure ventilation. The wound should never be packed because the negative pressure during inspiration can suck the dressing into the chest cavity. These considerations are not as important once the patient is in the ED, where endotracheal intubation and tube thoracostomy can be performed. Positive-pressure ventilation can then be started without the fear of producing a tension pneumothorax, and the patient can be prepared for definitive surgical repair.

Tension Pneumothorax. When the diagnosis of tension pneumothorax is suspected clinically, the pressure should be relieved immediately with needle thoracostomy, which is performed by inserting a large-bore (14-gauge or larger) catheter, at least 5 cm in length, through the second or third interspace anteriorly or the fourth or fifth interspace laterally on the involved side. Recent studies have suggested that some catheters may not be of sufficient length to penetrate the pleural space and that the lateral approach may be preferred. This method can be easily performed in the field or ED, allowing vital signs to improve during transport or preparation for a tube thoracostomy.[49]

The intubated patient in the ED who is receiving positive-pressure ventilation and external cardiac compressions is at particular risk for developing tension pneumothorax. Fractured ribs from cardiopulmonary resuscitation (CPR) can penetrate lung parenchyma and cause pneumothorax. Positive-pressure ventilation then increases intrapleural pressure and produces a tension pneumothorax. The earliest sign of this complication is an increase in resistance to ventilation. If the patient has vital signs, the blood pressure will fall and the central venous pressure (CVP) will rise. Misplacement of an endotracheal tube does not result in tension pneumothorax but, rather, asymmetry of breath sounds. If tension pneumothorax is suggested, the clinician should proceed with empirical emergent therapy.

Hemothorax

Epidemiology

Hemothorax, which is the accumulation of blood in the pleural space after blunt or penetrating chest trauma, is a common complication that may produce hypovolemic shock and dangerously reduce vital capacity. It is commonly associated with pneumothorax (25% of cases) as well as extrathoracic injuries (73% of cases).[50]

Box 45-2 Indications for Thoracotomy

- Initial thoracostomy tube drainage is more than 20 mL of blood per kilogram.
- Persistent bleeding at a rate greater than 7 mL/kg/hr is present.
- Increasing hemothorax seen on chest x-ray films.
- Patient remains hypotensive despite adequate blood replacement, and other sites of blood loss have been ruled out.
- Patient decompensates after initial response to resuscitation.

Anatomy and Pathophysiology

Hemorrhage from injured lung parenchyma is the most common cause of hemothorax, but this tends to be self-limited unless there is a major laceration. Specific vessels are less often the source of hemorrhage, with intercostal and internal mammary arteries causing hemothorax more often than hilar or great vessels. Bleeding from the intercostal arteries may be brisk, however, because they branch directly from the aorta.

Management

Close monitoring of the initial and ongoing rate of blood loss is performed. Immediate drainage of more than 1500 mL of blood from the pleural cavity is usually considered an indication for urgent thoracotomy. Perhaps even more predictive of the need for thoracotomy is a continued output of at least 200 mL/hr for 3 hours. General considerations for urgent thoracotomy are outlined in Box 45-2.[51]

Clinical Features

Depending on the rate and quantity of hemorrhage, varying degrees of hypovolemic shock will be manifested. Tactile fremitus is decreased, and breath sounds are diminished or absent.

Diagnostic Strategies

The upright chest radiograph remains the primary diagnostic study in the acute evaluation of hemothorax. A hemothorax is noted as meniscus of fluid blunting the costophrenic angle and tracking up the pleural margins of the chest wall when viewed on the upright chest x-ray film. Blunting of the costophrenic angles on upright chest radiograph requires at least 200 to 300 mL of fluid. The supine view chest film is less accurate, and it may be more difficult to make the diagnosis with the patient in this position. Unfortunately, this is often the only film available because of the patient's unstable condition. In the supine patient, blood layers posteriorly, creating a diffuse haziness that can be rather subtle, depending on the volume of the hemothorax (Fig. 45-11). With a massive hemothorax, the large volume of blood can create a tension hemothorax, with signs and symptoms of both obstructive and hemorrhagic shock (Fig. 45-12).

As is the case with pneumothoraces, US has much greater sensitivity than chest radiography in the detection of a small hemothorax, but CT scanning has the highest sensitivity, with some studies reporting up to a 25% incidence of hemothoraces diagnosed by CT that were not detected on chest radiography (Fig. 45-13).[7] Perhaps more important, almost half of these occult hemothoraces underwent drainage with tube thoracostomy.[52] Furthermore, one drawback of ultrasonography for the identification

www.ketabpezeshki.com 66485457-66963820

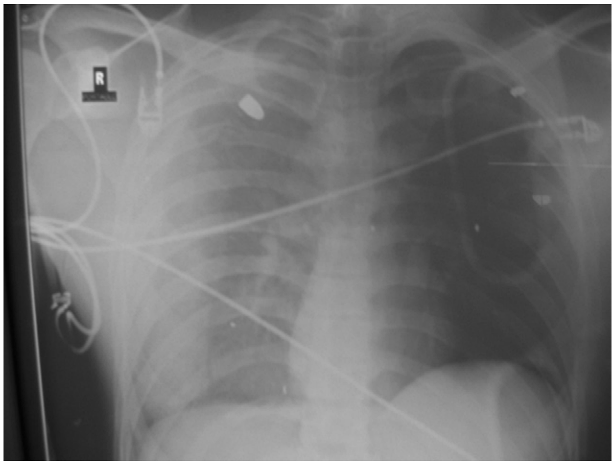

Figure 45-11. Hemothorax secondary to gunshot wound. Note haziness over right hemithorax with bullet seen in right upper lobe.

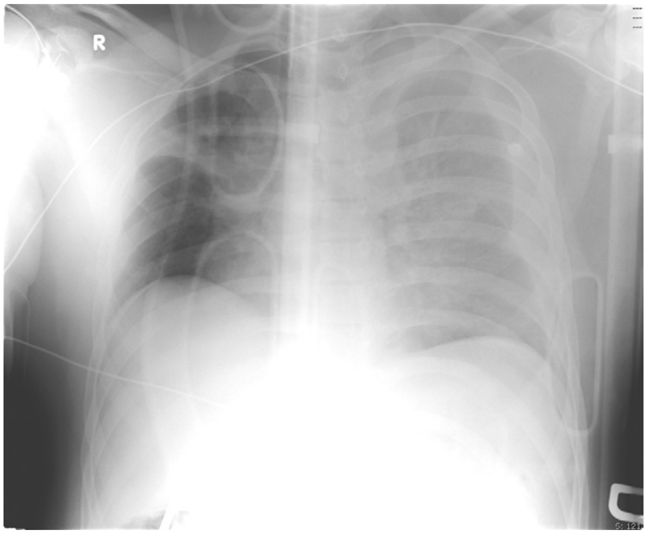

Figure 45-12. Tension hemothorax.

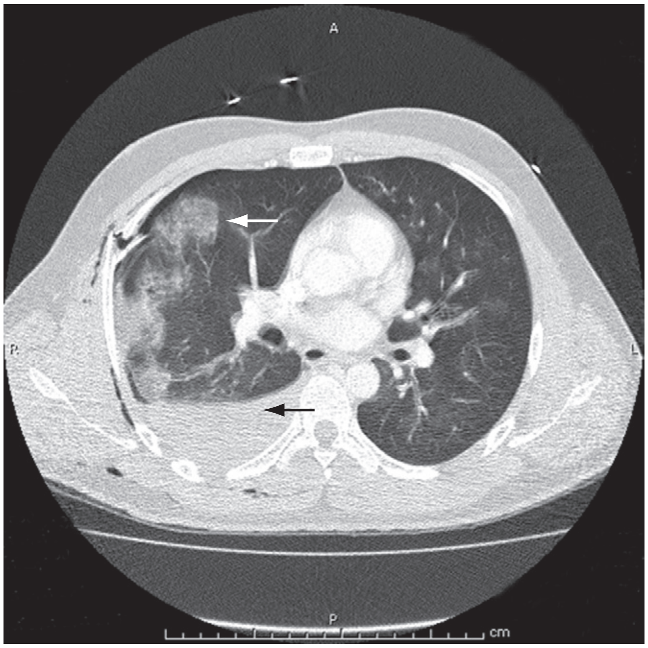

Figure 45-14. Rib fracture resulting in pneumothorax, with associated hemothorax (*bottom arrow*) and pulmonary contusion (*top arrow*) seen on chest computed tomography scan.

of traumatic hemothorax is that associated injuries readily seen on chest radiographs in the trauma patient, such as fractures or a widened mediastinum, are not readily identifiable on chest ultrasonography (Fig. 45-14). However, chest radiography and early bedside ultrasonography usually detect clinically significant hemothoraces and should routinely be performed. Delayed hemothorax may be associated with significant morbidity because the residual blood may serve as a nidus for the development of empyema or fibrothorax.

Management

Treatment of hemothorax consists of restoring the circulating blood volume, controlling the airway as necessary, and evacuating the accumulated blood. Tube thoracostomy allows constant monitoring of the blood loss, and serial chest radiographs help monitor lung reexpansion. A large-bore tube (36-F to 40-F) should be inserted in the fifth interspace at the anterior axillary line and connected to underwater seal drainage and suction (20-30 mL H_2O).

Although small hemothoraces may be observed in stable patients, a moderate hemothorax or any hemothorax in an unstable or symptomatic patient requires tube thoracostomy. Severe or persistent hemorrhage requires thoracostomy or open thoracotomy. Studies are required to better delineate the size of a hemothorax detected on CT scan that requires tube thoracostomy drainage.

Autotransfusion has been successfully used in tube thoracostomy. Recent simplification and commercial availability of the equipment have made autotransfusion feasible in most EDs. Autotransfusion also eliminates the risk of incompatibility reactions and transmission of certain diseases such as hepatitis C. Because the majority of blood loss occurs immediately after tube thoracostomy placement, autotransfusion apparatus should be immediately available in the ED.

As a result of the increasing frequency of chest CT scans, it has been found that there may be a greater frequency of misplaced thoracostomy tubes than is evident on conventional chest

www.ketabpezeshki.com 66485457-66963820

radiographs. Almost 25% of patients in one series subsequently required operative intervention as a result of complications from penetration of the lung parenchyma from tube thoracostomies.[53] However, the true incidence of complications that require some surgical intervention remains unknown (Fig. 45-15).

Although beyond the scope of emergency medicine, mention is made of the role of thoracoscopy. Video-assisted thoracic surgery (VATS) is particularly useful for evaluation and evacuation of retained hemothorax, control of bleeding from intercostal vessels, and diagnosis and repair of diaphragmatic injuries.[54,55] As surgeons gain more experience with the technique, VATS will likely become more widely used for other indications as well, given the decreased morbidity and length of hospital stay compared with open thoracotomy.[56]

TRACHEOBRONCHIAL INJURY

Epidemiology

Tracheobronchial injuries may occur with either blunt or penetrating injuries of the neck or chest. Penetrating injuries tend to be more obvious because of their nature, alerting both the patient and the physician, whereas blunt injuries can be occult. MVCs are the most frequent mechanism causing tracheobronchial injury, accounting for more than half of all cases.[57]

Although there has been an increase in the occurrence of tracheobronchial disruption, it is still a relatively rare injury, occurring in fewer than 3% of patients with significant chest injury. Its associated mortality rate is reported to be approximately 10%, although mortality rates are significantly affected by associated injuries and the timing of diagnosis and surgical repair.[58,59]

Anatomy and Pathophysiology

Tracheobronchial injuries caused by knife wounds develop almost exclusively from wounds in the cervical trachea, whereas gunshot wounds may damage the tracheobronchial tree at any point. Intrathoracic injury to the tracheobronchial tree occurs most commonly from blunt trauma. These injuries may result from direct blows, shearing stresses, or burst injury. A direct blow to the neck may crush the cervical trachea against the vertebral bodies and transect the tracheal rings or cricoid cartilage. Shear forces on the trachea will produce injury at the carina and the cricoid cartilage, which are its relatively fixed points.

Sudden deceleration of the thoracic cage, as occurs in a decelerating auto accident, pulls the lungs away from the mediastinum, producing traction on the trachea at the carina. When the elasticity of the tracheobronchial tree is exceeded, it ruptures. It has also been suggested that if the glottis is closed at the time of impact, the sudden increase in intrabronchial pressure will rupture the tracheobronchial tree. Regardless of the mechanism, more than 80% of these injuries occur within 2 cm of the carina.

Clinical Features

Massive air leak through a chest tube, hemoptysis, and subcutaneous emphysema should suggest the diagnosis of major airway damage. Subcutaneous emphysema is typically the most common physical finding.[57] Auscultation of the heart may reveal Hamman's crunch if air tracks into the mediastinum. Hamman's crunch is a crunching, rasping sound that is synchronous with the pulse and is best heard over the precordium. It is the result of the heart beating against air-filled tissues. Patients with tracheobronchial disruption have one of two distinct clinical pictures. In the first group of patients, the wound opens into the pleural space, producing a large pneumothorax. A chest tube fails to evacuate the space and reexpand the lung, and there is continuous bubbling of air in the underwater seal device.

In the second group of patients there is complete transection of the tracheobronchial tree but little or no communication with the pleural space. A pneumothorax is usually not present. The peribronchial tissues support the airway enough to maintain respiration, but within 3 weeks granulation tissue will obstruct the lumen and produce atelectasis. These patients are relatively free of symptoms at the time of injury but weeks later have unexplained atelectasis or pneumonia. Radiographic signs in either group of patients are pneumomediastinum, extensive subcutaneous emphysema (Fig. 45-16), pneumothorax, fracture of the upper ribs (first through fifth), air surrounding the bronchus, and obstruction in the course of an air-filled bronchus.

Diagnostic Strategies

When tracheobronchial injury is suspected, bronchoscopy should be performed. Fiberoptic bronchoscopy is the most reliable means of establishing the diagnosis and determining the site and extent of the injury. However, CT scan has been shown to have high sensitivity in detecting tracheobronchial injury.[60]

www.ketabpezeshki.com 66485457-66963820

Bronchopleural fistula (a communication between a bronchus and the lung parenchyma) can occur as a complication of tracheobronchial disruption and in some cases has been treated successfully via the fiberoptic bronchoscope. A mediastinal fluid collection, evidence of mediastinitis, or both may be noted on chest CT. However, bronchoscopy is usually preferred to make the diagnosis.

Management

If possible, endotracheal intubation over a bronchoscope should be performed because it allows visualization of the tube as it passes beyond the site of injury. In attempting blind intubation, care is taken not to place the endotracheal tube through a transected airway into the soft tissue or a false passage or to convert a partial tracheal tear into a complete one.

The standard treatment for tracheobronchial injury has been surgery. However, conservative medical treatment of such injuries has been reported for tracheobronchial injury patients who meet strict selection criteria. These include patients without any major symptoms, including esophageal-associated injuries, progressive subcutaneous or mediastinal emphysema, severe dyspnea requiring intubation, difficulty with mechanical ventilation, pneumothorax with an air leak through the chest drains, open tracheal injuries, or mediastinitis.[46] In most cases, thoracotomy with intraoperative tracheostomy and surgical repair of the disrupted airway should be performed as soon as possible.

DIAPHRAGMATIC INJURY

Epidemiology

Diaphragmatic rupture is present in 1 to 6% of major thoracic injuries. Diaphragmatic rupture occurs most commonly after blunt thoracoabdominal trauma, such as occurs in MVCs or falls from heights, but can also occur from penetrating trauma.[61]

Anatomy and Pathophysiology

Diaphragmatic hernia is a herniation of abdominal structures within the thoracic cavity through a defect on the diaphragm. Because of pressure gradients across the diaphragm, these injuries are associated with herniation and a potential risk of strangulation of abdominal viscera, especially the small bowel. Signs and symptoms may not occur during the initial admission and may be delayed for as long as months to years.[62] In one study, delayed recognition of incarcerated diaphragmatic hernia after stab wounds to the lower chest and upper abdomen was associated with a mortality rate of 36%.[63]

When diaphragmatic rupture secondary to blunt trauma occurs, the right hemidiaphragm is ruptured in 15 to 24% of cases and the left in 70 to 80%. Five percent to 8% of cases are bilateral. It is generally accepted that this is because of the protective effect of the liver on the right hemidiaphragm against herniation of small bowel. In penetrating injuries of the upper abdomen and lower thorax, such as from gunshot wounds and stab wounds, possible diaphragmatic injury should be considered.

In cases of blunt injury, the raised pressure within the abdominal cavity causes the tear of the diaphragm, and a pressure difference of generally 5 to 10 mm Hg forces the abdominal organs through the diaphragmatic defect. Because blunt trauma can cause multiple organ injuries, these coexisting injuries can mask the more silent diaphragmatic injuries, and diaphragmatic rupture may be initially overlooked. Over time, negative intrathoracic pressure generated by inspiration tends to draw abdominal contents into the thorax. This effect is lost with the use of intubation and positive-pressure ventilation. Because there is also a plugging effect of the viscera over the defect, migration of the abdominal organs within the thorax is usually delayed, so these injuries are diagnosed in only 10% of cases in the acute phase.[63] An overlooked diaphragmatic injury in the acute phase sometimes manifests as respiratory compromise or a hernia with obstruction, incarceration, or perforation of bowel months or decades later.

Diagnostic Strategies

The diagnosis and management of diaphragmatic injuries are problematic because these injuries cause variable clinical and radiologic signs. Accurate diagnosis of traumatic diaphragmatic hernia is essential because prompt surgical repair is the treatment of choice.

Chest radiography is the first imaging study to determine the presence of diaphragmatic rupture, but a plain chest radiograph immediately after the accident arouses suspicion about the diagnosis of a ruptured diaphragm in only 20 to 34% of cases. CT examination of the abdomen and chest is a very useful and reliable tool in the evaluation of blunt diaphragmatic injury, but the injury site and type affect its sensitivity.[64] CT can demonstrate findings consistent with diaphragmatic injury, such as diaphragmatic discontinuity, intrathoracic herniation of abdominal contents, and waistlike constriction of abdominal viscera (the "collar sign"). An isolated omental herniation is clearly detectable on nonenhanced CT because of its fatty nature and crescent shape, and a CT with intravenous contrast will more clearly reveal the contrast-enhancing omental vessels. If the stomach or intestine is herniated, distended intestinal segments containing air-fluid levels are visualized on the supine position images. It is reported that helical CT can be used to detect 78% of left-sided and 50% of right-sided injuries.[65] Albeit highly unusual, efflux of peritoneal lavage fluid through a thoracostomy tube is also diagnostic of a diaphragmatic hernia.

Although magnetic resonance imaging is not useful in most traumatic diaphragmatic hernia cases owing to its relatively long duration and increased sensitivity for motion artifact, it is preferred in selected patients, especially in delayed traumatic diaphragmatic herniation cases from small penetrating injuries. In hemodynamically stable patients with penetrating left thoracoabdominal trauma, the incidence of injury to the diaphragm is very high, and thoracoscopy or laparoscopy is recommended for the diagnosis and repair of a diaphragmatic injury.[61,66,67] Patients with right-sided small penetrating lesions typically do not experience herniation because of the protective effect of the dome of the liver on the right side.

Management

Diaphragmatic injuries may be a predictor of serious associated injuries in trauma and a marker of severity,[4] but they do not ordinarily require urgent repair. The treatment of choice is surgery. CT scan should identify the site and extent of herniation, herniated organs, complications, and damage to associated organs. Although they are not without complications, laparoscopy and thoracoscopy may be used for diaphragmatic hernia repair.

The incidence of diaphragmatic involvement after penetrating left-sided thoracoabdominal injury is high, making nonoperative, expectant management of these patients potentially unsafe. Mandatory evaluation of the diaphragm with laparoscopy to exclude injury in all asymptomatic, hemodynamically normal patients is recommended.[68] In the absence of significant hemoperitoneum or other factors preventing adequate visualization of the diaphragm, laparoscopy or thoracoscopy is a sensitive means of excluding occult diaphragmatic injury in these patients. When significant hemoperitoneum is encountered on laparoscopy or other factors are present that prohibit adequate evaluation of

www.ketabpezeshki.com 66485457-66963820

the diaphragm, conversion to an open exploration should be considered to fully visualize the diaphragm at risk and exclude additional injuries.

CARDIOVASCULAR TRAUMA

Blunt Cardiac Trauma

Epidemiology

Blunt cardiac injury usually results from high-speed MVCs in which the chest wall strikes the steering wheel. Other causes, such as falls from heights, crushing injuries, blast injuries, and direct blows, are less common. The significance of blunt injuries as a cause of myocardial or cardiac contusion was described more than 50 years ago by Bright and Beck.[69] Nevertheless, the diagnosis of a blunt injury to the heart remains elusive because of the usual concomitant serious injuries to other body organs and, more important, because there is no gold standard for making the diagnosis.

The importance of detecting blunt myocardial injury lies in the recognition of associated potentially fatal complications. Life-threatening dysrhythmias, conduction abnormalities, congestive heart failure, cardiogenic shock, hemopericardium with tamponade, cardiac rupture, valvular rupture, intraventricular thrombi, thromboembolic phenomena, coronary artery occlusion, ventricular aneurysms, and constrictive pericarditis have all been reported as complications.

Anatomy and Pathophysiology

Blunt cardiac trauma may be viewed as part of a continuous spectrum (i.e., myocardial concussion, contusion, infarction, and rupture).[70] Myocardial concussion occurs when a blunt injury to the interior chest produces a “stun” response in the myocardium. No permanent cellular injury occurs, but transient clinical effects may result. Myocardial contusion is the least severe form of injury that can be demonstrated pathologically. Cellular injury occurs with extravasation of red blood cells into the muscle wall, along with localized myocardial cellular necrosis. Permanent myocardial damage is rare.[71] Traumatic myocardial infarction (MI) results from either direct trauma to the coronary arteries or a severe contusion of the myocardium, leading to irreversible cellular injury and ultimately cell death. Direct injury to the coronary arteries via laceration, thrombosis, or spasm is thought to be the most common mechanism for traumatic MI. Cardiac rupture is obviously the most severe form of blunt cardiac injury.

Myocardial Concussion

The term *myocardial concussion* or *commotio cordis* is used to describe an acute form of blunt cardiac trauma that is usually produced by a sharp, direct blow to the midanterior chest that stuns the myocardium and results in brief dysrhythmia, hypotension, and loss of consciousness.[72] If the patient survives the initial dysrhythmia, there are no lasting or discernible histopathologic changes, and it is difficult to make the definitive diagnosis of myocardial concussion. This presumptively explains those cases of sudden death after a blow to the chest in which no histopathologic changes in the myocardium are demonstrated at autopsy.[72]

If prolonged cellular dysfunction occurs, it may result in a nonperfusing rhythm, such as asystole or ventricular fibrillation, and irreversible cardiac arrest. There are a number of documented cases of successful resuscitation with rapid provision of CPR and the use of an automated external defibrillator in children who were struck in the chest while playing Little League baseball.[73]

Myocardial Contusion

Epidemiology

Myocardial contusion has been a diagnosis describing a very poorly understood and nebulous condition. Decades of research and widely varied clinical practice have failed to produce a consensus regarding its diagnosis, complication rate, and proper disposition. The incidence of myocardial contusion varies from 3 to 55% in reported series of severe closed-chest trauma, depending on the criteria used for establishing the diagnosis.[74,75]

Anatomy and Pathophysiology

Several mechanisms have been postulated by which the heart may be injured in cases of blunt trauma. A direct blow to the chest transmits energy through the ribs to the spine. When a large force is applied to the chest wall over an extended period, the sternum is displaced posteriorly and the heart is compressed between the sternum and vertebrae or an elevated diaphragm. Either can result in cardiac injury. Increased intrathoracic pressure from a direct blow to the chest may contribute to the injury. In addition, compression of the abdomen and pelvis may displace abdominal viscera upward and result in cardiac injury.

A myocardial contusion is histologically characterized by intramyocardial hemorrhage, edema, and necrosis of myocardial muscle cells. These histologic findings are similar to those seen in acute MI. An accumulation of edema and cellular infiltrate in the wall of the heart may cause a decrease in ventricular compliance, resulting in cardiac dysfunction.

Most myocardial contusions heal spontaneously, with resolution of cellular infiltrate and hemorrhage leading to scar formation. Small pericardial effusions occur in more than 50% of cases of contusion, usually during the second week. These are probably caused by pericardial irritation, and they neither imply significant cardiac injury nor increase the risk of tamponade, and they require no therapy such as pericardiocentesis. A fibrinous reaction at the contusion site may also occur, resulting in pain, a friction rub, and adhesion to the pericardium. In a few cases, the reabsorption of the hematoma is accompanied by necrosis of the ventricular wall, which may result in a delayed rupture of the myocardium or a scarred and weakened area with subsequent development of a ventricular aneurysm. If necrosis occurs, it will usually be manifested in the second week after injury and is one of the causes of delayed sudden death after blunt trauma to the chest. However, this is a rare phenomenon.

Clinical Features

Myocardial contusion manifests clinically as a spectrum of injuries of varying severity. Although the majority of patients with myocardial contusion have external signs of thoracic trauma (e.g., contusions, abrasions, palpable crepitus, rib fractures, or visible flail segments), the absence of thoracic lesions decreases the suspicion but never excludes cardiac injury. Other associated injuries may include pulmonary contusion, pneumothorax, hemothorax, external fracture, and great vessel injury. The most sensitive but least specific sign of myocardial contusion is sinus tachycardia, which is present in approximately 70% of patients with documented myocardial contusions and is a very common vital sign in trauma patients. A reduction in cardiac output, which can be clinically insignificant or manifest as pronounced cardiogenic shock, may occur in patients with significant cardiac contusion.

www.ketabpezeshki.com 66485457-66963820

Diagnostic Strategies

Significant controversy exists regarding the importance and manner of establishing the diagnosis of myocardial contusion in otherwise hemodynamically stable patients.[76]

Even when the diagnosis of a myocardial contusion is considered, confirming the diagnosis without a true gold standard is problematic. Clinical evidence is often nonspecific, especially in the setting of multiple trauma. Patients may have dysrhythmias or ST wave changes caused by significant hypoxia as a result of pulmonary injuries or blood loss, which resolve once the hypoxemia or blood loss has been corrected. Likewise, severe intracranial injury, electrolyte abnormalities, and excessive vagal or sympathetic tone may give rise to dysrhythmias or an abnormal ECG. Under these conditions, ECG abnormalities may not represent true myocardial damage. On the contrary, they may cause one to overlook the potential for traumatic cardiac injury. One large series of blunt trauma patients found that blunt cardiac injury was a significant risk factor for cardiac dysrhythmia.[76]

Because myocardial contusion cannot be positively identified short of biopsy or autopsy, there is much confusion regarding the role of the various laboratory and imaging studies used to diagnose myocardial injury. Multiple studies using cardiac biomarkers have been unhelpful in establishing or excluding the diagnosis. Furthermore, the vast majority of myocardial contusions probably do not cause clinically significant complications. Based on mechanism alone, the relative risk of a life-threatening dysrhythmia is far too low to warrant routine admission to rule out myocardial contusion in all patients with blunt chest trauma. Several studies suggest that very few patients diagnosed with myocardial contusion develop cardiac complications requiring therapeutic intervention or a change in management. Therefore a routine cardiac workup is not indicated in most blunt thoracic trauma victims.[77] The usefulness of diagnostic studies is to identify patients at low risk who can be safely discharged from the ED and not to diagnose the presence of a myocardial contusion.

Diagnostic strategies that have been used to "diagnose" myocardial contusion and assess the risk of complications and the need for admission include ECG, biochemical cardiac markers (serum creatine kinase [CK-MB] isoenzyme levels or troponin levels), two-dimensional echocardiography, and CT scan.

Electrocardiogram. The ECG after blunt chest trauma may be normal or may show nonspecific abnormalities. Because of its anterior position in the thorax and proximity to the sternum, the right ventricle is far more likely to be injured than the left ventricle. The standard 12-lead ECG is relatively insensitive to right ventricular damage, as demonstrated by pathologic evidence of cellular damage in patients with normal ECGs. A cardiac contusion usually results in moderate right ventricular damage with only minor electrical changes, which can easily be missed on ECG. Right-sided ECGs (the addition of V_4R) have not been found to be of any benefit.[78]

Little is known about the relative risk of dysrhythmia as a function of the ECG abnormality, and any new ECG finding warrants consideration of further diagnostic studies or admission for further monitoring. A severely injured right ventricle may cause a right bundle branch block, usually transient. Less commonly, various degrees of atrioventricular block have been documented after blunt chest trauma. Sinus tachycardia and ventricular and atrial extrasystoles are the most frequently reported rhythm disorders. More serious arrhythmias, such as atrial fibrillation, ventricular tachycardia, and ventricular fibrillation, occur less often but may acutely compromise the hemodynamic state or even result in sudden death.[76]

A few cases of delayed life-threatening dysrhythmia have been reported up to 12 hours after injury, and patients may develop less lethal dysrhythmias up to 72 hours after injury. The onset of ECG changes may be delayed up to 48 hours after injury, and all ECG changes usually resolve in 4 to 60 days.[76] The presence of ECG abnormalities is neither specific enough to confirm the diagnosis of myocardial contusion nor reliable enough to predict subsequent complications.

Cardiac Enzymes. Because myocardial contusion is histologically characterized by intramyocardial hemorrhage and necrosis of myocardial muscle cells, similar to those seen in acute MI, cardiac enzymes were the first screening tool used to detect myocardial injury. CK is nonspecifically increased in trauma patients owing to associated skeletal muscle injury, and CK-MB levels have also been found to be falsely elevated and therefore are very nonspecific in multitrauma patients. Thus the use of CK-MB levels is of very limited utility in screening for myocardial contusion and is no longer recommended.[79-81]

Although serum cardiac troponin is highly specific for myocardial injury in the setting of acute MI, elevated troponin levels have been found to have much lower sensitivity for myocardial contusion, and they may occur in the absence of a significant direct myocardial contusion.[81] However, such studies are limited because no true gold standard exists to confirm the diagnosis. Several studies have suggested that the combination of a normal troponin level and a normal 12-lead ECG has a negative predictive value to "rule out" myocardial contusion of 100%, suggesting that these patients do not need any other workup or monitoring specific to possible myocardial contusion.[81] If there is concern because of nonspecific ECG abnormalities or an elevated troponin level on initial evaluation in the ED, a secondary measurement after 4 to 6 hours should be performed to reliably exclude myocardial injury.[80,81]

Echocardiography. Echocardiography provides a means of direct visualization of cardiac structures and chambers. Because contused myocardium resembles infarcted myocardial tissue both histologically and functionally, two-dimensional echocardiography is useful in diagnosing myocardial contusion by evaluating wall motion abnormalities. It is also useful in identifying associated lesions, such as thrombi, pericardial effusion, and valvular disruption. Furthermore, echocardiography offers the practical advantages of being portable, noninvasive, and easy to use at the bedside. If patients have painful chest wall injuries, transthoracic echocardiography may be limited. In these cases, transesophageal echocardiography (TEE) is an alternative.[74]

Management

Appropriate workup and treatment of the patient with suspected myocardial contusion begins with accurate out-of-hospital evaluation. Paramedics should observe and relay information to the ED concerning mechanism of injury, status of the motor vehicle, steering wheel and dashboard damage, use of seat belts and air bags, speed of the vehicle before the accident, and position of the patient when found. Pertinent clinical data to be recorded include vital signs, level of consciousness, cardiac rhythm, and the presence of chest wall trauma.

The value of admitting and carefully monitoring patients with suspected mild (i.e., hemodynamically asymptomatic) cardiac contusions is not supported. The latest studies do suggest that troponin levels are very helpful in risk stratification of patients suspected of having myocardial contusion.[77,80,81] One such strategy is to perform emergent echocardiography for all severely injured patients with hemodynamic instability who are suspected to have structural damage to the heart and/or great vessels. Elevated troponin levels or ECG abnormalities indicate a higher risk of developing cardiac complications. A similar recommendation exists for severely injured patients with a sternal fracture, although the presence of an isolated sternal fracture is not necessarily a sign of cardiac injury. Increased troponin levels or ECG abnormalities

www.ketabpezeshki.com 66485457-66963820

indicate a higher risk of developing cardiac complications. Further investigation, including echocardiography, serial ECGs, and serial troponin levels, is recommended.

In patients who have minor injuries and are otherwise asymptomatic, elevated troponin levels and minor ECG abnormalities do not necessarily indicate a clinically significant myocardial contusion. Very few of these patients will develop complications. However, normal troponin levels (4-6 hours after injury) along with normal (or unchanged) ECGs correlate with minimal risk of cardiac complications. Therefore in-hospital monitoring may be limited to those patients with significant, acute ECG abnormalities, elevated troponin concentrations, or both. Serial ECGs and troponin levels should be obtained until the results return to normal.

Echocardiography is rarely required in this low-risk subset of patients who have minor injuries and are otherwise asymptomatic. If the patient's clinical status deteriorates or there is inconsistency between the troponin levels and ECG changes, echocardiography can be very useful to rule out structurally significant myocardial injuries, which may include wall motion or valvular abnormalities.

On admission, treatment of a suspected myocardial contusion should be similar to that of an MI: intravenous line, cardiac monitoring, and administration of oxygen and analgesic agents. Dysrhythmias should be treated with appropriate medications as per current Advanced Cardiac Life Support guidelines.[82] No data exist to support prophylactic pharmacologic agents for dysrhythmia suppression. Measures should be taken to treat and prevent any conditions that increase myocardial irritability (e.g., metabolic acidosis). Thrombolytic agents and aspirin are contraindicated in the setting of acute trauma. In rare instances there may be an acute MI associated with trauma, which can arise from lacerations or blunt injury to the coronary arteries. These cases should be managed by percutaneous coronary intervention (PCI), with cardiothoracic surgery for definitive repair as indicated.

In the setting of depressed cardiac output caused by myocardial contusion, judicious fluid administration is required. Dobutamine may be useful after optimal preload is ensured. Intra-aortic balloon counterpulsation has been used successfully in refractory cardiogenic shock. The priority is to be certain that the decreased cardiac output is not the result of other undiagnosed injuries, particularly aortic rupture.

Prognosis

The prognosis of a patient with myocardial contusion depends on the character and magnitude of the initial trauma, the size and location of the contusion, the preexisting condition of the coronary arteries, and, most important, any other organ trauma and its complications. Major morbidity and mortality correlate most closely with the number of associated serious injuries. Recovery without complications is the usual course.

Myocardial Rupture

Myocardial rupture refers to an acute traumatic perforation of the ventricles or atria, but it may also include a pericardial rupture or laceration or rupture of the interventricular septum, interatrial septum, chordae, papillary muscles, valves, and lacerated coronary arteries. A delayed rupture of the heart may also occur weeks after nonpenetrating trauma, probably as a result of necrosis of a contused or infarcted area of myocardium.

Epidemiology

High-speed MVCs are responsible for most cases of traumatic myocardial rupture. Myocardial rupture is almost always immediately fatal and accounts for 15% of fatal thoracic injuries. It has been estimated that blunt cardiac rupture accounts for 5% of the 50,000 annual highway deaths in the United States.[1] In various series, the incidence of cardiac rupture in cases of blunt chest trauma ranges from 0.5 to 2%.[83] The most common cause of death in cases of nonpenetrating cardiac injuries is myocardial rupture. Approximately one third of these patients have multiple chamber rupture, and one fourth have an associated ascending aortic rupture. Bright and Beck reviewed 152 autopsy cases of traumatic cardiac ruptures and found that 20% of patients survived 30 minutes or more, which would have allowed them to reach the operating room had the problem been recognized.[69] The first report of successful repair of blunt cardiac rupture was published in 1955 and involved a patient with right atrial rupture.[84]

Anatomy and Pathophysiology

The chambers most commonly involved in cardiac rupture are the ventricles, with right ventricular rupture being most common. Ruptures of the atria are less common, with right atrial rupture being more common than left. Multiple chamber involvement occurs in 20% of patients.[83] Twenty percent of nonsurvivors have concomitant aortic rupture.

A rupture occurs during closure of the outflow track when there is ventricular compression of blood-filled chambers by a pressure sufficient to rupture the chamber wall, septum, or valve. This is the most likely mechanism for ventricular rupture when injury occurs in diastole or early systole concomitant with maximal ventricular distention. The atria are most susceptible to rupture by sudden compression in late systole when these chambers are maximally distended with venous blood and the atrial ventricular valves are closed. Other proposed mechanisms of rupture include (1) deceleration shearing stresses acting on the "fixed" attachment of the inferior and superior vena cava at the right atrium; (2) upward displacement of blood and abdominal viscera from blunt abdominal injury that causes a sudden increase in intracardiac pressure; (3) direct compression of the heart between the sternum and vertebral bodies; (4) laceration from a fractured rib or sternum; and (5) complications of a myocardial contusion, necrosis, and subsequent cardiac rupture.

Because of the nature of the mechanisms involved in cardiac rupture, associated multisystem injuries are common. More than 70% of reported survivors of myocardial rupture have other major associated injuries, including pulmonary contusions, liver and spleen lacerations, closed head injuries, and major fractures. Twenty percent of nonsurvivors have concomitant aortic ruptures.[83]

The immediate ability of the patient to survive cardiac rupture depends on the integrity of the pericardium. Two thirds of patients with cardiac rupture have an intact pericardium and are protected from immediate exsanguination. These patients may survive for variable periods but eventually develop significant hemopericardium and pericardial tamponade. One third of patients with cardiac rupture have associated pericardial tears and succumb promptly to exsanguination.

Occasionally, patients survive if the pericardial tear is small or the rupture is small enough to seal itself. A small pericardial laceration may allow partial and intermittent release of tamponade while still controlling bleeding. In one series of patients with confirmed myocardial rupture, 40% of patients had isolated rupture of the right atrium. The overall mortality rate was 81%, with none of the patients with two-chamber rupture, ventricular rupture, or absence of vital signs on arrival at the ED surviving.[83]

Clinical Features

The clinical presentation of a patient who has sustained a myocardial rupture is usually that of cardiac tamponade or severe

www.ketabpezeshki.com 66485457-66963820

hemorrhage. Rarely, a patient is seen with a large hemothorax, hypotension, and hypovolemia, suggesting rupture with associated pericardial tear. A patient with an intact pericardial sac and developing tamponade displays physical findings of tamponade, usually with subsequent clinical deterioration. Initial inspection of the torso may reveal little more than a bruised area over the sternum or no external physical evidence. More often, however, signs of significant chest trauma or other associated injuries will be present, indicating a mechanism of injury that could result in myocardial rupture. Auscultation may reveal a harsh murmur, known as a "bruit de moulin," which sounds like a splashing mill wheel. This is caused by pneumopericardium.

In a review of survivors of myocardial rupture, common symptoms and signs included hypotension (100%); elevated CVP (95%); tachycardia (89%); distended neck veins (80%); cyanosis of the head, neck, arms, and upper chest (76%); unresponsiveness (74%); distant heart sounds (61%); and associated chest injuries (50%).[83-86]

The following findings are suggestive of pericardial rupture:

1. Hypotension disproportionate to the suspected injury
2. Hypotension unresponsive to rapid fluid resuscitation
3. Massive hemothorax unresponsive to thoracostomy and fluid resuscitation
4. Persistent metabolic acidosis
5. The presence of pericardial effusion on echocardiography or elevation of CVP and neck veins with continuing hypotension despite fluid resuscitation

Diagnostic Strategies

Early use of ED US may facilitate the early diagnosis of cardiac rupture and pericardial tamponade.[87] The combination of shock and jugular venous distention (or an elevated CVP) in a patient with blunt chest trauma should immediately suggest pericardial tamponade. However, in patients with coexistent hemorrhage from other injuries, JVD may be absent. Other considerations include tension pneumothorax, right ventricular myocardial contusion, superior vena cava obstruction, and ruptured tricuspid valve. Sonographic visualization of pericardial fluid in this setting should be followed by emergent thoracotomy (Fig. 45-17).

A chest radiograph should be obtained immediately in all cases of acute, blunt chest injuries. Although this study usually does not help diagnose cases of myocardial rupture, it notes the presence of other intrathoracic injuries (e.g., hemothorax, pneumothorax, and signs of possible aortic dissection). An increase in the size of the cardiac silhouette more commonly reflects preexisting disease or valvular incompetence with chamber enlargement caused by increased filling pressures. ECG changes may occur with myocardial injury, but these are often nonspecific for myocardial rupture. Early use of bedside echocardiography in the ED should be performed in any case of suspected cardiac rupture, pericardial tamponade, a previously undiagnosed murmur, or shock unexplained by other causes (e.g., exsanguination).

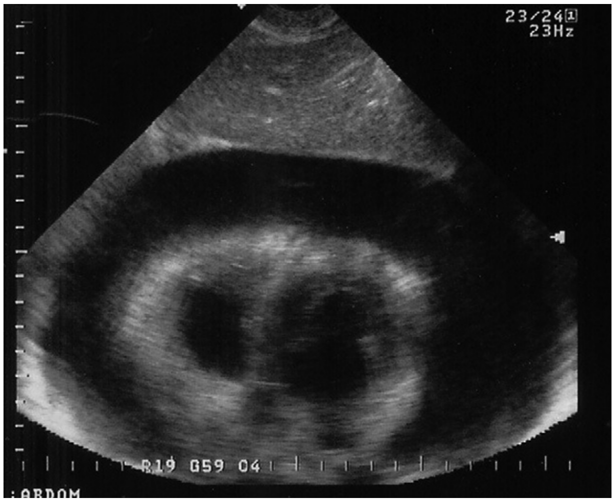

Figure 45-17. Echocardiogram demonstrating pericardial fluid with cardiac tamponade.

Management

When nonhospital medical personnel evaluate a patient who has sustained blunt chest trauma, they should concentrate on rapid transport and pay attention for any signs of pericardial tamponade. En route to the hospital, the possibility of a tension pneumothorax should be considered as well.

In the ED, treatment of patients with a myocardial rupture is directed toward immediate decompression of cardiac tamponade and control of hemorrhage. Pericardiocentesis may be effective in cases of a small rupture, but it is usually performed as a diagnostic or temporizing therapeutic procedure until surgical correction can be undertaken. Emergency thoracotomy and pericardiotomy may be required in the ED if the patient has rapidly deteriorating vital signs or a cardiac arrest. After emergency thoracotomy and pericardiotomy, the myocardial rupture should be controlled until the patient can be transported to the operating room for definitive repair. Hemorrhage from a ruptured atrium can often be controlled by finger occlusion or application of a vascular clamp. Insertion of a Foley catheter through the defect, followed by inflation of the balloon and traction on the catheter, may also control the bleeding. Ventricular rupture can usually be controlled by direct digital pressure or by suturing with nonabsorbable vascular sutures.

Cardiopulmonary bypass is commonly required in only 10% of successful repairs of myocardial rupture.[83] Therefore, for patients with suspected myocardial rupture, it is appropriate to undertake emergency thoracotomy in institutions that have qualified surgeons but no immediate access to cardiopulmonary bypass.

Prognosis

Reported survival rates for patients with myocardial rupture and an intact pericardium vary widely. Although only a small number of survivors of ventricular rupture had been previously reported,[81,82,84] a small case series reported that four out of a total of five patients with blunt cardiac rupture who arrived at the ED with vital signs ultimately survived.[85] Most survivors of cardiac rupture are patients with atrial rupture, including one patient with multiple atrial tears. Most undergo surgical repair within 3 or 4 hours of injury. Approximately 60% of successful repairs have been performed more than 60 minutes after injury.

Miscellaneous Cardiac Injuries

The occurrence of intracardiac injuries that result from blunt chest trauma (e.g., septal defects or valvular injuries) is less common. Valve rupture may involve the chordae tendineae, leaflets, or papillary muscles. Involvement of the aortic valve is more common than involvement of the mitral or tricuspid valves. Mitral and tricuspid valve injuries associated with a pericardial laceration have been reported in a survivor of blunt chest trauma. The exact incidence of cardiac valvular injuries and septal defects is unknown. Serial echocardiography and monitoring of ECG changes as well as frequent auscultation may aid in earlier diagnosis of these lesions.

www.ketabpezeshki.com 66485457-66963820

Clinical Features

The clinical presentation of these patients depends on which valve or septum is involved and whether coincident cardiac injuries are present. A complete rupture of the mitral valve usually results in immediate death. The clinical presentation of an incomplete rupture depends on the hemodynamic state of the patient. Cardiogenic shock is common. Findings of acute mitral insufficiency and rapidly developing pulmonary edema are usually predominant. A loud, harsh diastolic murmur with frank left heart failure suggests acute aortic insufficiency. If the patient is in a low output state, the associated thrills and murmurs of aortic or mitral insufficiency may not be appreciated. The signs and symptoms of tricuspid insufficiency that follow a rupture of that valve may be less dramatic or even minimal. Examination may reveal only a diastolic murmur and prominent V waves of the jugular venous pulsations.

Patients with isolated septal defects may have minimal symptoms of exertional dyspnea or severe progressive shock and pulmonary edema, depending on the size and location of the defect. Dysrhythmias and conduction defects are rare because the lower muscular septum is principally involved. The typical holosystolic murmur along the left sternal border is an important clue in diagnosing a ventricular septal defect, but it may not appear for days or months after the injury. Serial echocardiography and ultimately cardiac catheterization for both valvular and septal defects are necessary for a definitive diagnosis.

Management

The therapy selected depends primarily on how well the patient tolerates the insult. Many years may elapse before operative treatment is required. In cases of ventricular septal defects, a period of observation is valuable because there have been reports of the spontaneous closure of traumatic ventricular septal defects months after the injury when the defects and resultant shunt are small. Medical therapy commonly relieves the symptoms of congestive failure, but intractable or progressive heart failure or the development of pulmonary hypertension usually indicates the need for surgery.

Penetrating Cardiac Injury

Penetrating cardiac injuries are one of the leading causes of death in the setting of urban violence. Patients with penetrating cardiac injury who survive to arrive at the hospital have an overall mortality rate of almost 80%.[88] Improvements in emergency medical services systems during the past few years, along with an emphasis on rapid transport, are responsible for an increasing number of cardiac injury patients arriving in impending or full cardiopulmonary arrest at busy urban trauma centers. The proportion of gunshot wounds versus stab wounds varies widely in reported case series, depending on the location of the trauma center.

The right ventricle is affected more often (43%) than the left ventricle (34%) owing to its anterior anatomic location. The left or right atrium is affected in 20% of cases.[89] One third of penetrating cardiac wounds affect multiple chambers, and survival is much worse in these cases. In 5% of cases, a coronary artery is lacerated, although these injuries usually involve a distal segment of the artery and rarely produce significant acute MI when they are ligated. More proximal coronary artery lacerations require coronary bypass.[90] Rarely, the interventricular septum, a valve, papillary muscle, or chordae tendineae are lacerated, producing an acute shunt or valvular insufficiency. These lesions are poorly tolerated and can quickly produce massive pulmonary edema and cardiogenic shock.

Box 45-3 Indications for Emergency Department Thoracotomy

Systolic blood pressure below 50 mm Hg after fluid resuscitation
Severe shock with clinical signs of cardiac tamponade

Blunt Trauma
Cardiac arrest in the emergency department

Miscellaneous
Suspected air embolus

Two conditions may occur after penetrating heart injury: (1) exsanguinating hemorrhage if the cardiac lesion communicates freely with the pleural cavity, or (2) cardiac tamponade if the hemorrhage is contained within the pericardium. Patients with exsanguinating wounds frequently die before they reach medical attention, or they have rapidly progressive hemorrhagic shock on presentation, culminating in cardiac arrest. This presentation is most typically seen in patients sustaining gunshot wounds to the heart. Cardiac tamponade is a life-threatening condition but appears to offer some degree of protection and increased survival in patients with penetrating cardiac wounds. These patients often require immediate resuscitation by ED thoracotomy (EDT) if they meet the criteria listed in Box 45-3.

Acute Pericardial Tamponade

Epidemiology

The reported incidence of acute pericardial tamponade is approximately 2% in patients with penetrating trauma to the chest and upper abdomen; it is rarely seen after blunt chest trauma. It occurs more commonly with stab wounds than with gunshot wounds, and 60 to 80% of patients with stab wounds involving the heart develop tamponade.[89] Patients with acute pericardial tamponade can deteriorate in minutes, but many can be saved if proper steps are taken.

Anatomy and Pathophysiology

The primary feature of a pericardial tamponade is an increase in intrapericardial pressure and volume. As the volume of the pericardial fluid encroaches on the capacity of the atria and ventricles to fill adequately, ventricular filling is mechanically limited, and thus the stroke volume is reduced. This results in decreased cardiac output and ultimately diminished arterial systolic blood pressure and decreased pulse pressure. As little as 60 to 100 mL of blood and clots in the pericardium may produce the clinical picture of tamponade. Concomitantly, CVP rises because of the mechanical backup of blood into the vena cava.

Several compensatory mechanisms then occur. The heart rate and total peripheral resistance rise in an attempt to maintain adequate cardiac output and blood pressure. A less effective compensatory response, resulting in a greater rise in CVP, is an increase in venomotor tone caused by contractions of the smooth muscles within the wall of the vena cava.

The diagnosis of pericardial tamponade should be suspected in any patient who has sustained a penetrating wound or blunt trauma to the thorax or upper abdomen. One is never certain of the trajectory of the bullet or the length, force, and direction of a knife thrust on initial evaluation. Obviously, wounds directly over the precordium and epigastrium are more likely to produce a cardiac injury resulting in tamponade than those in the posterior or lateral thorax. Nevertheless, it is assumed that a penetrating

www.ketabpezeshki.com 66485457-66963820

wound, particularly a gunshot wound, anywhere in the thorax or upper abdomen may have injured the heart. Rapid bedside echocardiography, performed as part of the standard FAST examination, easily detects a pericardial effusion causing cardiac tamponade.[91,92]

Clinical Features

Patients with cardiac tamponade may initially appear deceptively stable if the rate of bleeding into the pericardial space is slow or if the pericardial wound allows intermittent decompression. Other patients may complain primarily of difficulty breathing, which suggests pulmonary rather than cardiac pathology.

The physical findings of pericardial tamponade are hypotension, distended neck veins, and, rarely, distant or muffled heart tones.[93] This so-called *Beck's triad* is sometimes difficult to demonstrate clinically, especially in the midst of a major resuscitation with concomitant hypovolemia, when the neck veins may be flat.[91] Although the most reliable signs of pericardial tamponade are an elevated CVP (>15 cm H_2O) in association with hypotension and tachycardia, bedside echocardiography performed as part of the FAST examination rapidly identifies pericardial tamponade and has largely replaced the use of CVP measurements to make the diagnosis. Echocardiography also distinguishes pericardial tamponade versus tension pneumothorax when the triad of elevated CVP, hypotension, and tachycardia is present.

Acute pericardial tamponade may be seen with three distinct clinical pictures. If the hemorrhage is confined to the pericardial space, the patient is initially normotensive but will have a tachycardia and elevated CVP. If untreated, most of these patients go on to develop hypotension. If significant hemorrhage has occurred outside the pericardial sac, either through a tear in the pericardium or from associated trauma, the clinical picture is that of hypovolemic shock with hypotension, tachycardia, and a low CVP. If the CVP rises to a level of 15 to 20 cm H_2O with volume replacement and hypotension and tachycardia persist, the presence of a pericardial tamponade is considered. Also considered are other causes, such as a tension pneumothorax, Valsalva maneuver, or pulmonary edema secondary to fluid overload.

The third clinical picture is that of an intermittently decompressing tamponade. In this case, intermittent hemorrhage from the intrapericardial space occurs, decompressing and partially relieving the tamponade. The clinical picture may wax and wane depending on the intrapericardial pressure and volume and total blood loss. In general, this condition is compatible with a longer survival than are the first two clinical presentations.

Pulsus paradoxus is defined as an excessive drop in systolic blood pressure during the inspiratory phase of the normal respiratory cycle. This sign may be an additional clue to the presence of pericardial tamponade, but it is often difficult to measure during an intensive resuscitation or in the presence of shock.

Diagnostic Strategies

Ultrasound. US, which is now widely available in EDs throughout the world, enables rapid, accurate, and noninvasive diagnosis of pericardial tamponade.[92,94] This study can be performed at the bedside in the ED during the initial resuscitation of the patient as part of the FAST examination. Although the sonographic definition of tamponade is the simultaneous presence of pericardial fluid and diastolic collapse of the right ventricle or atrium, the presence of pericardial fluid in a patient with chest trauma is highly suggestive of pericardial hemorrhage (see Fig. 45-17). An indirect sonographic sign of tamponade is the demonstration of a dilated inferior vena cava in a hypotensive patient. EDs in which cardiac ultrasonography is performed with subcostal and long parasternal views have reported a sensitivity of 98.1% and a specificity of 99.9% for the detection of pericardial effusion.[92,93] Because US is noninvasive and extremely accurate, its immediate availability in the initial phase of a major trauma resuscitation can be very helpful in detecting pericardial fluid before the patient deteriorates hemodynamically.

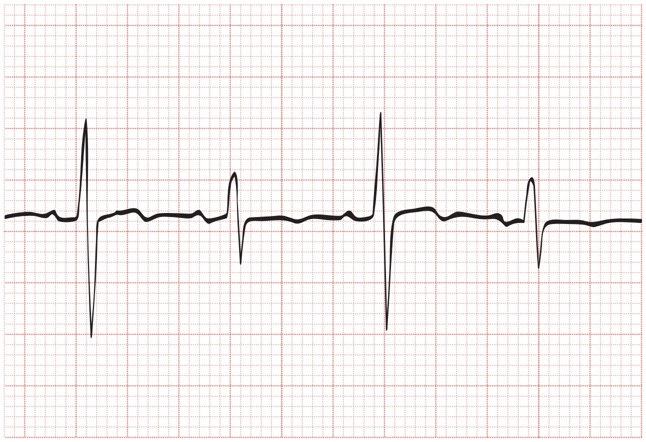

Figure 45-18. Lewis lead electrocardiogram revealing total electrical alternans of the QRS complexes. (From Sotolongo RP, Horton JD: Total electrical alternans in pericardial tamponade. Am Heart J 101:853, 1981.)

Electrocardiography. Many ECG changes of pericardial tamponade have been described in the literature, but few are diagnostic, and each is more likely to be seen with chronic rather than acute tamponade. Electrical alternans has been reported to be a highly specific marker of pericardial tamponade. Electrical alternans is an ECG change in which the morphology and amplitude of the P, QRS, and ST-T waves in any single lead alternate in every other beat (Fig. 45-18). The postulated cause is the mechanical oscillation of the heart in the pericardial fluid, which is called the *swinging heart phenomenon.* In uncomplicated pericardial effusion, the heart swings back and forth but returns to approximately the same position before the next systole. Electrical alternans does not occur in this situation.

Echocardiographic studies have revealed that when fluid accumulates to a critical extent and cardiac tamponade ensues, the frequency of cardiac oscillation may abruptly decrease to half the heart rate. The cardiac position will alternate, with the heart returning to its original position with every other beat, and electrical alternans may be seen. Electrical alternans, when present, is pathognomonic for tamponade. However, it is much more common in chronic pericardial effusions that evolve into a tamponade, and it is rarely seen in acute pericardial tamponade. However, low amplitude of the QRS complexes may be seen as a result of the presence of pericardial effusion.

Radiography. The radiographic evaluation of the cardiac silhouette in acute pericardial tamponade generally is not helpful, unless a traumatic pneumopericardium is present. Because small volumes of hemopericardium lead to tamponade in the acute setting, the heart will typically appear normal. This is in contrast to the "water-bottle" appearance of the heart with chronic pericardial effusion. Usually the latter condition is tolerated for a long period.

Management

Out-of-Hospital Care. Field treatment for cases of pericardial tamponade is essentially the same as that outlined for any victim of major trauma. The diagnosis of tamponade should be suspected by the location of penetrating wounds or by the patient's poor response to vigorous volume resuscitation. Tension pneumothorax, which is much more common, may mimic certain aspects of

www.ketabpezeshki.com 66485457-66963820

acute pericardial tamponade. If the patient is in extremis or the clinical condition rapidly deteriorates, consideration should be given to performing a needle thoracostomy, which, if not therapeutic, suggests pericardial tamponade under the appropriate clinical presentation by virtue of "diagnosis of exclusion." Expedient transport to the nearest trauma center should be of paramount concern.

Emergency Department. When the patient arrives in the ED, volume expansion with crystalloid solution via two or three large-bore (14- or 16-gauge) catheters should be established immediately. The presence of a pneumothorax or hemothorax, which is often associated with penetrating cardiac trauma, is treated expeditiously with tube thoracostomy. Bedside echocardiography should be performed as quickly as possible to establish the diagnosis of pericardial tamponade, which then should be followed by emergent surgical repair.

There is increasing controversy regarding the role of pericardiocentesis. In the past, it was recommended that pericardiocentesis be performed for both diagnostic and therapeutic reasons. Aspiration of as little as 5 to 10 mL of blood may result in dramatic clinical improvement. However, it should be emphasized that pericardiocentesis is not a benign or invariably successful procedure. Blood in the pericardial space tends to be clotted, and aspiration may not be possible. Possible complications include the production of pericardial tamponade, the laceration of coronary artery or lung, and induction of cardiac dysrhythmias. Whenever possible, pericardiocentesis should be performed under sonographic guidance because this approach will increase the success rate and decrease the incidence of complications. A pigtail catheter may be introduced into the pericardial space for repeated aspirations while preparations are underway to quickly transport the patient to the operating room for definitive therapy. If pericardiocentesis is unsuccessful or the clinical status deteriorates, and if acute pericardial tamponade remains important in the differential diagnosis, thoracotomy should be performed as quickly as possible.[81] Patients with penetrating cardiac injury invariably require surgical repair. The location (operating room vs. ED) and timing (immediate vs. urgent) depend on the patient's clinical status.

Emergency Department Thoracotomy. EDT is a drastic, dramatic, and potentially lifesaving procedure in which emergency physicians should be proficient. Although the procedure is not described in detail here, a few technical points merit discussion. A left lateral incision is preferred because it is rapidly accomplished; allows the best exposure of the heart, aorta, and left hilum; and facilitates open cardiac massage and internal defibrillation[95] (Fig. 45-19). With right-sided or multiple injuries, it may be necessary to extend the incision across the sternum and right chest wall, creating a "clamshell" incision. The internal mammary arteries need to be ligated if this maneuver restores effective perfusion. After the heart is sufficiently exposed, the pericardium is vertically incised anterior to the phrenic nerve. Release of a tamponade may rapidly restore cardiac output. The heart is then delivered through the pericardium, and penetrating wounds are identified.

There are several alternatives for repairing cardiac wounds. Small wounds can be compressed by digital pressure to control bleeding en route to the operating room. If the injury is quite large, balloon tamponade can be achieved by applying gentle traction on a Foley catheter inserted into the wound with the balloon inflated with saline. This can temporarily stop the hemorrhage to allow suture repair of the injury (cardiorrhaphy) or to gain time while the patient is transferred to the operating room for a more definitive surgical procedure. Lacerations of the atria can be temporarily controlled with a vascular clamp.[95]

Suture of cardiac wounds over pledgets is the time-honored and effective technique but is technically more difficult and more time-consuming. The use of a monofilament suture, such as 2-0 Prolene, is recommended. Some trauma surgeons recommend

Figure 45-19. Emergency department thoracotomy.

stapling cardiac wounds with standard skin staplers because this technique has been shown to be much quicker and equally effective in closing these wounds, and there is also a report on the use of a collagen mesh attached with fibrin glue mesh to rapidly repair a ventricular laceration.[96,97]

Care is taken to avoid ligating coronary arteries during the repair. Direct insertion of a large-bore catheter (e.g., a 5-F catheter) into the left atrial appendage provides a route for rapid infusion of fluids. If the heart is empty or the patient fails to respond to rapid fluid administration, the aorta is cross-clamped to divert cardiac output to the brain and heart. Prolonged ischemia and severe acidosis often result in postresuscitation myocardial depression with ineffective contraction and diminished cardiac output. Thus the cross-clamp should be temporarily released every 30 to 45 minutes to minimize ischemic complications.

Indications for Emergency Department Thoracotomy. Although it is often tempting to perform EDT on all traumatic arrest victims in the ED, there are many cases in which patients have virtually no chance of survival.[98] In addition, EDT is costly; requires the undivided attention of all personnel in the ED, diverting care from other, more salvageable patients in critical condition; and poses a risk to ED personnel for injury from needle sticks and other blood-contaminated exposures. Consequently, guidelines have been established by the National Association of EMS Physicians and the American College of Surgeons Committee on Trauma (ACSCOT) to withhold EDT or terminate resuscitative efforts on scene.[99] These guidelines, along with the most recent Advanced Trauma Life Support text, include withholding EDT for patients in cardiopulmonary arrest secondary to blunt trauma (see Box 45-3).[100]

However, several recently published case series have questioned whether these guidelines are overly restrictive. One large, multicenter study reported three neurologically intact survivors of EDT who had asystole at ED arrival (all of whom had pericardial tamponade) and five survivors after blunt traumatic arrest who had mild to no neurologic deficits, and another study also reported

www.ketabpezeshki.com 66485457-66963820

survivors of EDT who did not meet the traditional survival predictors.[101,102] Other authors have noted that some patients who survive EDT may be suitable organ donors.[103] Patients with penetrating trauma with signs of life in the field, even if only electrical activity on cardiac monitor or agonal respirations, are candidates for EDT if transport times are less than 10 minutes.[102-104]

Prognosis

After penetrating wounds to the heart, several factors adversely affect survival, including gunshot wound mechanisms and wounds that involve the left ventricle, multiple cardiac chambers, intrapericardial great vessels, or one or more coronary arteries. The factors favorable to survival include stab wound mechanisms with minor perforations, isolated right ventricular wounds, a systolic blood pressure greater than 50 mm Hg on arrival at the ED, and the presence of cardiac tamponade.

Survival rates after EDT have been correlated with the mechanism and location of injury, field and transport times, the duration of arrest, and the physiologic status of the patient in the out-of-hospital and hospital settings. Although reported survival rates after EDT vary widely, they are consistently higher in victims with isolated cardiac injuries secondary to stab wounds versus gunshot wounds.[99-102,104]

A meta-analysis of the literature found that EDT had an overall survival rate of 7.4%, with normal neurologic outcomes noted in 92.4% of surviving patients. Survival rates according to mechanism of injury were 9% for penetrating injuries and 1% for blunt injuries. When penetrating injuries were further separated, the survival rates were 17% for stab wounds and 4% for gunshot wounds. The presence of pericardial tamponade is a favorable prognostic finding.[105,106]

Blunt Aortic Injury

Epidemiology

Blunt aortic injury is a life-threatening injury, usually resulting from sudden deceleration, usually from automobile crashes. Other mechanisms of injury include pedestrians struck by automobiles, motorcycle crashes, airplane crashes, and falls from heights.[107] In an analysis of automobile crash data, the impact was most often head-on (72%), followed by side impact (24%) and rear impact (4%).[108] Despite the improvement in and increased use of restraint systems, the overall incidence of blunt aortic injury associated with fatal automobile crashes has remained unchanged over the past decade.[109]

Blunt aortic injury includes a spectrum of lesions, ranging from a small intimal tear to frank rupture, which usually cause rapid lethal hemorrhage. The most common sites of injury are the aortic isthmus and the ascending aorta just proximal to the origin of the brachiocephalic vessels.[107] Sixty percent to 90% of patients with blunt aortic injury die at the site of accident or within hours of hospital admission.[109,110] However, an increasing number of patients arrive at a treatment facility because of improvement in out-of-hospital care, more aggressive resuscitation in the field, and rapid transportation to a trauma center. The early survival rate of such patients depends on the initial resuscitation and/or the timeliness and correct choice of the diagnostic procedures. A rapid and accurate diagnosis is thus mandatory to optimize treatment and maximize patient survival.

Anatomy and Pathophysiology

Blunt aortic injury encompasses various histologic lesions. Minor blunt aortic injuries (grade 1, intramural hematoma or limited intimal flap) and major blunt aortic injuries (grade 2, subadventitial rupture or modification of the geometric shape of the aorta; and grade 3, aortic transection with active bleeding or aortic obstruction with ischemia) can be differentiated by TEE. Whereas minor blunt aortic injuries appear to have a good prognosis, major blunt aortic injuries involve the entire depth of both the intimal and the medial layers and may lead to adventitial rupture, resulting in sudden death at the scene of the accident or during the first hours of hospitalization.[111]

Several theories about the mechanism of aortic rupture have predominated in the literature. The descending thoracic aorta is relatively fixed and immobile because of its tethering by intercostal arteries and the ligamentum arteriosum. With sudden deceleration, the more mobile aortic arch swings forward, producing a shearing force or "whiplash effect" on the aorta at the isthmus. A bending stress at the isthmus, created by sudden lateral oblique chest compression, may also result in rupture by causing flexion of the aortic arch on the left mainstem bronchus and the pulmonary artery. It has been suggested that the forces created by the whiplash effect or lateral oblique compression may not be sufficient to provoke aortic tears. It is now postulated that those injuries may be caused by inferior and posterior rotation of anterior thoracic osseous structures (manubrium, first rib, and medial clavicles), pinching and shearing the interposed aorta as they strike the vertebral column.

Rupture of the ascending aorta just distal to the aortic valve likely occurs through a different mechanism. At the time of rapid deceleration and chest compression, the heart is displaced into the left posterior chest, which causes a shearing stress just above the aortic valve. A sudden increase in intra-aortic pressure, "the water-hammer effect," may also cause an explosive rupture of the aorta at this location. Involvement of the coronary ostia with coronary artery occlusion may occur in association with tears to the ascending arch. The intraluminal pressure tolerance of the aorta may be exceeded in a high-speed motor vehicle crash. It is likely that a combination of the preceding mechanisms accounts for the multiple aortic ruptures that have been found in 20% of traffic accident victims examined at autopsy.[109]

A total of 80 to 90% of aortic tears occur in the descending aorta at the isthmus, just distal to the left subclavian artery (Fig. 45-20).[107,110,111] Less common sites of involvement are the

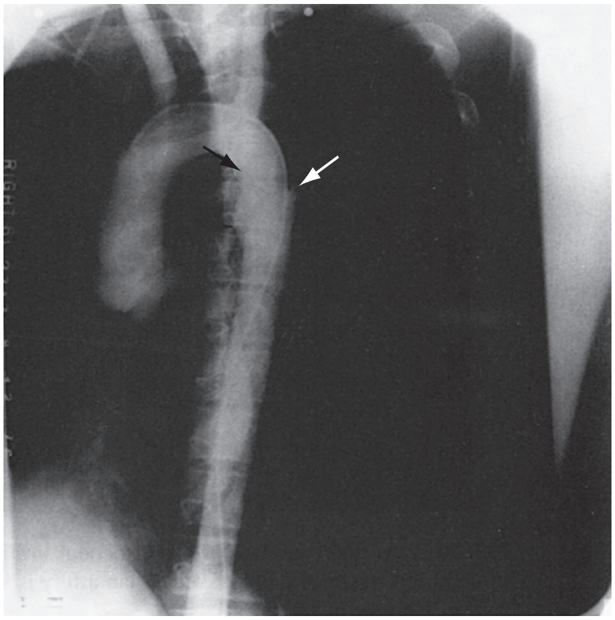

Figure 45-20. Aortogram shows tear in aorta *(arrows)* at the most common location, at or just distal to takeoff point of left subclavian artery, which is not visualized.

www.ketabpezeshki.com 66485457-66963820

ascending aorta, the distal descending aorta at the level of the diaphragm, the midthoracic descending aorta, and the origin of the left subclavian artery. Although ruptures of the ascending aorta are much less common than those of the descending aorta, they have a 70 to 80% incidence of associated lethal cardiac injuries. This is in contrast to ruptures at the isthmus, which have a 25% incidence of associated cardiac injuries. Lethal cardiac injuries commonly include pericardial tamponade, aortic valve tears, myocardial contusion, or coronary artery injuries. Passenger ejection, pedestrian impact, severe falls, and crush injuries commonly result in ascending thoracic aortic ruptures. Survival long enough to be evaluated in the ED is rare among patients who sustain an ascending aortic rupture.[111]

Aortic rupture may occur from causes other than high-speed MVC deceleration. Rupture has been documented as a complication of external cardiac massage and has been known to occur after fracture-dislocations of the thoracic spine, presumably as a result of direct shearing force. Vertical deceleration injuries resulting from falls can cause a rupture of the ascending aorta by producing an acute lengthening of the ascending aorta. This is the likely mechanism responsible for aortic rupture in the setting of airplane and elevator accidents. Direct kicks by animals, crush injuries, sudden burial by landslide, and air bag deployment have also been reported as causes of aortic rupture. Direct compression of the compliant thorax has been postulated to contribute to aortic rupture in children. Displaced fractures of the sternum, ribs, and clavicle have also been shown to directly lacerate the aorta.

Clinical Features

The possibility of aortic disruption is considered in every patient who sustains a severe deceleration injury, because approximately 30% of surviving patients with blunt aortic injury will die within the first 24 hours without treatment.[112] This is especially true if the automobile was moving in excess of 45 mph or if there is evidence of severe blunt force to the chest (e.g., from a damaged steering wheel).[109] In the case of any moderate- or high-speed motor vehicle accident, it is imperative that paramedics carefully evaluate the extent of damage to the vehicle, the complaints of the victims, and the physical manifestations of blunt chest trauma. This information should be promptly relayed to the emergency physician.

Despite the severe nature of the injury, the clinical manifestations of an aortic rupture are often deceptively meager. Associated pulmonary, neurologic, orthopedic, facial, and abdominal injuries are commonly present. Coexisting injuries can mask the signs and symptoms of an aortic injury or divert the physician's attention away from the more lethal aortic rupture. The absence of any external evidence of a chest injury does not eliminate the possibility of an aortic tear. One third to one half of patients reported in the literature have no external signs of chest trauma.[107,111]

The most common symptom is interscapular or retrosternal pain. It is often found in nontraumatic aortic dissection but is present in only 25% of patients with a traumatic aortic disruption. Other symptoms described in the literature but uncommonly present include dyspnea resulting from tracheal compression and deviation, stridor or hoarseness caused by compression of the laryngeal nerve, dysphagia caused by esophageal compression, and extremity pain caused by ischemia from decreased arterial flow.

Clinical signs are uncommon and nonspecific. Generalized hypertension, when present, may be an important clinical sign. Sympathetic afferent nerve fibers, located in the area of the aortic isthmus, are capable of causing reflex hypertension as a response to a stretching stimulus. A less common clinical finding is the acute onset of upper extremity hypertension, along with absent or diminished femoral pulses. This pseudocoarctation syndrome has been reported to occur in up to one third of these patients and is attributed to compression of the aortic lumen by a periaortic hematoma.

The presence of a harsh systolic murmur over the precordium or posterior interscapular area may be heard in up to one third of patients. The murmur is thought to result from the turbulent flow across the area of transection. A less commonly encountered physical finding is a swelling at the base of the neck caused by the extravasation of blood from the mediastinum, which results in an increased neck circumference or a pulsatile neck mass. Other clinical signs suggestive of aortic rupture include lower extremity pulse deficit and lower extremity paralysis. Initial chest tube placement output in excess of 750 mL is also suggestive of aortic rupture, especially if the hemothorax is left sided. However, the physical examination is neither sensitive nor specific for aortic injury, preventing accurate diagnosis without ancillary studies.

Diagnostic Strategies

Chest Radiography. Radiography of the chest is a valuable tool when aortic rupture is suspected. Many patients have died because the presence and significance of radiographic findings were not appreciated. An increase in the width of the superior mediastinum is the most sensitive sign and is found in 50 to 92% of aortic ruptures (Fig. 45-21).[113,114] However, specificity of this radiologic sign is as low as 10%.

Mediastinal widening may be caused by venous bleeding from a clavicle, thoracic spine, or sternal fracture; pulmonary contusions; a previous mediastinal mass; a misplaced CVP catheter; or magnification caused by the anteroposterior and supine position of a portable chest radiograph. Hence the sign is not pathognomonic for aortic rupture.

Commonly cited guidelines for abnormal mediastinal widening include a mediastinal width greater than 6 cm in the erect posteroanterior film, greater than 8 cm in the supine anteroposterior chest film, or greater than 7.5 cm at the aortic knob or a ratio of mediastinal width to chest width greater than 0.25 at the aortic knob. There is disagreement regarding the reliability of these parameters in confirming or excluding aortic rupture. A subjective interpretation of mediastinal widening is more reliable than direct measurement of mediastinal width.[114] Positioning of the patient and the degree of inspiration are important factors in assessing

the mediastinum. Every effort should be made to obtain a standard upright inspiratory posteroanterior film, if clinically feasible, before a mediastinum is declared abnormal, to avoid false-positive interpretations.

Current literature is replete with various diagnostic radiologic criteria thought to be sensitive indicators of aortic rupture.[115,116] Several authors have shown that an interpretation of widened mediastinum and an obscured aortic knob are the most reliable signs of aortic rupture. The opacification of the clear space between the aorta and the pulmonary artery, displaced nasogastric tube, widened paratracheal stripe, or widened right paraspinal interface is thought to provide the most specific evidence for aortic rupture.[113,115,116] Others believe that deviation of the nasogastric tube to the right in combination with depression of the left mainstem bronchus below 40 degrees from the horizontal is the most reliable sign positively associated with the diagnosis.

Other reported radiologic signs of a ruptured aorta include left hemithorax, obliteration of the medial aspect of the left upper lobe apex (left apical pleural cap), deviation of the trachea to the right, and multiple rib fractures. Fractures of the first and second ribs, once classically described as highly suggestive of aortic injury, do not appear to be associated with increased risk compared with that of patients without these fractures.

Although previous reports suggested that a negative chest radiograph is highly predictive of a normal aortogram, several studies have challenged this widely held belief. Between 7 and 44% of patients with blunt aortic injury may have a normal mediastinum on chest radiography[117-119]; thus the sensitivity of a negative chest radiograph (i.e., normal mediastinum) is limited. These findings have led to the liberal use of helical chest CT scanning in patients with high-speed deceleration mechanisms of injury.[118]

Chest Computed Tomography Scan. Chest CT scanning has largely replaced the need for aortography to detect aortic rupture and is now the diagnostic test of choice.[120-122] The development of multidetector helical CT scanning in the early 1990s revolutionized trauma radiology with its speed and superior definition, thereby largely negating the negative results obtained with conventional scans. New helical CT scans have almost 100% sensitivity and specificity for rapidly detecting aortic injury while requiring only intravenous contrast administration (Figs. 45-22 and 45-23). A normal aortic contour on CT, even in the presence of a mediastinal hematoma, has been shown to be highly accurate in excluding thoracic aortic disruption (Figs. 45-24 and 45-25).[118,119,121]

A chest CT scan with intravascular contrast offers a number of advantages over aortography. It is noninvasive, provides significantly more information on other thoracic injuries than chest radiography, and can be performed more rapidly than angiography. At most centers, an immediate chest CT scan is readily available. In addition, in the group of patients with a widened mediastinum, CT evaluation may be useful in evaluating not only the aorta but also the spine because spinal fractures may be the

cause of a widened mediastinum. It is now recommended that all patients with a mechanism of injury suggestive of potential aortic injury undergo CT evaluation of the mediastinum, irrespective of chest radiographic findings.[118]

As a result of the improvements in CT scanning technology, more subtle aortic lesions are now being identified, which has led to the term "minimal aortic injury." A minimal aortic injury is defined as an aortic injury with an intimal flap less than 1 cm, and no or minimal periaortic mediastinal hematoma.[123] Up to 10% of patients with blunt aortic injury diagnosed on CT scan may have a minimal aortic injury. It is felt that minimal aortic injuries carry a relatively low risk of rupture. Some centers opt to follow these patients with serial CT scans. If the injury is associated with significant thrombus, periaortic hematoma, lumen encroachment, or pseudoaneurysm, many centers will then proceed to endograft coverage via interventional radiology.[123]

Transesophageal Echocardiography. TEE is an alternative method to CT scanning or aortography for establishing the diagnosis of aortic rupture.[124-126] It offers a number of advantages over other diagnostic studies: It is fast, does not require intravenous contrast or radiation exposure, provides concomitant evaluation of cardiac function, and can be performed in the ED. Sedation is necessary to avoid hypertension while the probe is inserted. TEE is contraindicated in patients with esophageal injury.

TEE allows identification of an intimal flap, as well as a periaortic hematoma (Fig. 45-26). When only a monoplane TEE is used, the upper portion of the ascending aorta represents a blind zone because of the interposition of the air-filled trachea. However, because the vast majority of injuries are located at the isthmus, TEE is highly accurate, with a reported sensitivity of 87 to 100% and a specificity of 98 to 100%.[124-126] When available, TEE offers an alternative to a chest CT scan as a diagnostic screening test for aortic injury.

In patients with severe blunt chest trauma, TEE and CT have been found to have similar diagnostic accuracy for the identification of surgical acute traumatic aortic injury. In addition, TEE also allows the diagnosis of associated cardiac injuries and is more sensitive than CT for the identification of intimal or medial lesions of the thoracic aorta.[126]

Aortic repair may be feasible based on TEE alone, but aortography is still needed when TEE results are equivocal, when TEE is not tolerated or contraindicated, or when other suspected vascular injuries require evaluation by arteriography.[111]

Intravascular Ultrasound. Intravascular US has been described in the detection of subtle injuries to the aorta. This modality involves a small US probe that is inserted through the femoral artery and guided up the aorta. Currently, availability is limited to a few trauma centers because the technique requires sophisticated equipment and is performed in the operating room or angiography suite. Preliminary data suggest that intravascular US is extremely sensitive and specific in detecting blunt aortic injury.[127,128]

Aortography. Aortography, long considered the gold standard for establishing the diagnosis of aortic disruption, has been replaced almost completely by high-resolution helical CT scanners.[129,130] The major objective for patients with a ruptured aorta is the early recognition of the lesion before adventitial disruption and exsanguination. Multiple aortic tears occur in 15 to 20% of cases, necessitating precise anatomic localization of these injuries. Before the widespread availability of helical CT scanners, aortography was recommended not only for patients with a widened mediastinum but also for those who had sustained significant blunt chest trauma and who had any of the radiologic signs previously mentioned. An aggressive approach is particularly warranted in elderly patients.

Aortography should be delayed in patients with more immediate life-threatening injuries to the abdomen, pelvis, and head. In circumstances in which aortography is be delayed, it is important to provide medical management and maintain the systolic blood pressure below 120 mm Hg with antihypertensive agents.[128]

High-quality aortography can be performed with the aid of a rapid film changer by directly injecting the contrast medium into the root of the aorta through a catheter. The procedure involves a risk of further damage to the aorta or other ruptured vessel if the catheter crosses the site of the injury; however, this risk can be reduced by use of meticulous technique, a soft-tipped C-curve guidewire, and fluoroscopy. Simultaneous coronary angiography is often indicated, particularly in patients with an aortogram that shows a tear in the ascending aorta, because involvement of the coronary ostia by the dissection or the presence of significant arteriosclerotic disease may warrant coronary artery bypass grafting together with surgical repair of the aorta.

As surgeons have gained more experience with the diagnostic capabilities of helical CT scanning, the need for preoperative angiography has declined. Aortography should now be reserved for high-risk patients with indeterminate helical chest CT scans.[118,130]

Management

Out-of-Hospital Management. In the out-of-hospital care of any patient who has sustained blunt chest trauma, evaluation for possible aortic rupture should concentrate on identifying a mechanism of injury compatible with aortic rupture and treating hypotension, tension pneumothorax, and pericardial tamponade. Immediate communication of the patient's condition and expeditious transport to a trauma center will increase the patient's chance for survival.

Emergency Department. Because of the ever-present risk of sudden free rupture and exsanguination, repair of the lesion should be performed as soon as the diagnosis is made. Management of the patient with multiple injuries who has documented rupture of the thoracic aorta depends on the nature of associated injuries. Surgical repair of the aortic rupture should be delayed in the presence of life-threatening intracranial or intra-abdominal injury or profuse retroperitoneal hemorrhage.[118] Consideration for delay of the procedure should be made for patients at high risk for infection (e.g., those who have extensive body surface burns,

www.ketabpezeshki.com 66485457-66963820

contaminated large open wounds, established sepsis, or severe respiratory insufficiency caused by thoracic trauma).

Careful regulation of blood pressure is mandatory until definitive surgical repair can be performed. If operative repair is delayed, the systolic blood pressure should be maintained between 100 and 120 mm Hg. The objective of lowering the blood pressure is to decrease the shearing jet effect of an elevated pulse pressure, thus decreasing the possibility of continued adventitial dissection and subsequent free rupture.[130]

Esmolol, a short-acting titratable beta-blocker, may be ideally suited for this purpose because, unlike nitroprusside sodium, it decreases the pulse pressure and minimizes the shearing effect on the intact adventitia of the aorta. If blood pressure is not adequately controlled, nitroprusside sodium can be added as a second agent after the pulse pressure has been decreased with a short-acting beta-blocker.

Surgical Techniques

Many surgical techniques have been described since the first successful repair by Passaro and Pace in 1959.[131] In those patients who survive operative repair, paraplegia from spinal cord ischemia has been a significant complication, traditionally affecting as many as 10 to 20% of such patients.[132,133] The major variable thought to be related to spinal cord ischemia and subsequent development of paraplegia has been aortic cross-clamp times.[134] Blunt aortic injury ranges from a simple tear (usually distal to the origin of the subclavian artery) to complex injuries involving the proximal aorta and branch vessels.

Many surgeons have reported the use of cardiopulmonary bypass techniques in surgical repair to allow for distal spinal cord perfusion with significantly reduced incidence of paraplegia.[135,136] This is especially true for patients with complex aortic injuries, for which the aortic cross-clamp times are typically prolonged.[130]

The pathologic condition found dictates the type of repair. A synthetic graft is often required because of extensive tension on the vessel walls or jagged torn ends of the vessel. Data on successful primary repair of aortic disruption are encouraging. The procedure requires less operative time and has a lower potential infection risk, blood loss through a prosthesis is avoided, the possibility of pseudoaneurysm formation is eliminated, and secondary embolism arising from mural thrombosis is avoided. Multiple tears of the descending thoracic aorta have been successfully repaired with the primary suture technique. Direct end-to-end anastomosis appears to be most feasible in the younger population.

For patients who arrive at the hospital alive but who have descending thoracic aortic injuries, the incidence of mortality during surgery ranges from 20 to 30%, and the paraplegia rate is 5 to 7%.[132,135,136] Younger patients have the highest survival rate. Mortality is related to the presence or absence of extensive dissection and to the preoperative condition of the patient.

Endovascular Repair

There is a growing body of evidence demonstrating the safety and efficacy of endovascular repair of traumatic aortic tears.[137-141] This involves the use of a stent placed through a femoral or iliac artery approach. Preliminary data indicate that success rates and complication rates are comparable if not better than those of traditional open surgical repairs and that the risk of major surgery and subsequent paraplegia from prolonged aortic clamping is significantly reduced with endovascular repair.[142] Emerging literature suggests that endovascular repair with stenting is replacing open repair as the treatment of choice for blunt aortic injury (see Fig. 45-26).[143-148]

ESOPHAGEAL PERFORATION

Epidemiology

Perforation of the esophagus has been called the most rapidly fatal perforation of the gastrointestinal tract because death is almost ensured if the diagnosis is delayed more than 24 hours.[149] The classic description of esophageal perforation resulting from forceful vomiting was published in 1724 by Boerhaave, and from 1724 to 1941 the occurrence of Boerhaave's syndrome was almost uniformly fatal.[150] In 1941 the first successful surgical treatment, a drainage procedure, was reported, and in 1947 the first successful closure of a ruptured esophagus was described. Since then, improved surgical techniques, a greater physician awareness leading to a more prompt diagnosis, the availability of more effective antibiotics, and better general supportive measures have reduced the mortality to approximately 20%.[151] Mortality data cited for perforation are affected by several variables, such as location (with perforations of the thoracic segment having the highest mortality rate), mechanism of injury, time elapsed between injury and diagnosis, the presence of preexisting esophageal disease, and general health of the patient.

Anatomy and Pathophysiology

The anatomic feature responsible for the prolonged morbidity and high mortality associated with esophageal perforation is the lack of an esophageal serosal covering that allows perforation at any level direct access to the mediastinum. Perforations in the upper or cervical esophagus enter the retropharyngeal space, where fascial planes extend from the base of the skull to the bifurcation of the trachea. Perforations in the midesophagus and lower esophagus enter directly into the mediastinum. Only the thin mediastinal pleura prevents free access to the entire pleural cavity, and this barrier is commonly overcome by continued drainage and the massive exudative inflammatory reaction induced by chemical and bacterial mediastinitis. When the mediastinal pleura is penetrated, the negative pressure generated by respiratory efforts tends to increase the soilage by promoting drainage from the gastrointestinal tract into the mediastinum and pleural space.

When esophageal rupture results from emetic pressure, as in cases of Boerhaave's syndrome, the intrinsic weakness of the left posterior distal esophagus is important. Other areas (including cervical, midthoracic, and infradiaphragmatic sites) have been reported only rarely to rupture secondary to emesis. In addition, the esophagus has three areas of anatomic narrowing: the cricopharyngeal muscle near the esophageal introitus, the level at which the esophagus crosses the left mainstem bronchus and the aortic arch, and the gastroesophageal junction. In the absence of a preexisting esophageal disease such as carcinoma, it is unusual for a perforation caused by a foreign body to occur anywhere other than at these three sites. Foreign bodies may cause perforation by direct penetration, pressure, or chemical necrosis.

Etiology

The most common causes of an esophageal perforation are shown in Box 45-4.

Iatrogenic

Most esophageal perforations are iatrogenic, most commonly as a complication of instrumentation (59% of all patients).[152] The rigid endoscope is the most common offender, particularly when general anesthesia is used. Although use of the flexible endoscope has made this complication less likely, the total number of perforations has increased as more procedures are performed. Injuries

www.ketabpezeshki.com 66485457-66963820

Box 45-4 Most Common Causes of Esophageal Perforation

1. Iatrogenic

4. Blunt or penetrating trauma
5. Spontaneous rupture (Boerhaave's syndrome)
6. Postoperative breakdown of anastomosis

tend to occur near either the cricopharynx or the cervical esophagus as the endoscope is inserted.[152] Endoscopic procedures that are too vigorous in the presence of a corrosive burn or carcinoma are also a common cause of iatrogenic esophageal injury.

Esophageal dilation performed for benign or malignant strictures of the esophagus is the second most common iatrogenic cause of esophageal perforations.[153] Increasing the dilator size too rapidly during these procedures may lead to perforation. The preexisting fibrotic process that resulted in the stricture tends to scar the surrounding mediastinal tissues, however, limiting free access to the mediastinum provided by many other perforations. In the ED, nasotracheal or nasogastric intubations are the most common causes of iatrogenic perforation, with the perforation usually occurring in the pyriform sinus. In a closed claims analysis published in 1999, esophageal injuries by anesthesiologists were overwhelmingly associated with difficult intubations.[154] Risk factors for a difficult airway include obesity, cervical arthritis, haste, and improper muscle relaxation. Claims involving airways that were classified as "nondifficult" involved other esophageal instrumentation, such as a nasogastric tube, esophageal dilator, or esophageal stethoscope. In all cases, esophageal injuries were more severe than any other type of airway injury sustained during airway maneuvers.

The use of an esophageal obturator airway was also associated with occasional esophageal trauma, specifically midesophageal perforation. Use of the esophageal obturator airway's successors, the laryngotracheal Combitube and the King airway, do not seem to be associated with trauma more severe than occasional esophageal abrasions or contusions.[155]

Several cases of esophageal rupture secondary to compressed air have been reported, including two cases of pharyngoesophageal perforation secondary to gas in carbonated beverages and in tartaric acid–sodium bicarbonate mixtures administered to treat esophageal food impactions. Esophageal perforation has also been caused by placement of a cervical fixation device and secondary to the Heimlich maneuver.

Foreign Bodies

Foreign bodies can cause an esophageal injury by direct laceration, by pressure necrosis, or during endoscopic removal.[156] Small perforations tend to seal without sequelae, but pressure necrosis or lacerating injuries provide ample access to the mediastinum.[153] Foreign bodies usually lodge in the cervical esophagus, but if a distal stricture is present, this too is a common site. In children younger than 4 years, the cricopharyngeal narrowing is the usual point of foreign body impaction. After age 4 years, most objects pass this region and traverse the remaining normal esophagus. In adults, a foreign body impaction, especially in cases of repeated episodes, raises the possibility of a stricture and warrants further investigation.

In elderly patients, foreign bodies commonly enter the esophagus because of a loss of oral tactile sensation resulting from intoxication or a poorly fitting set of dentures.[152] Inadequate dentures may also lead to the swallowing of large pieces of poorly chewed food. Other esophageal foreign bodies include sharp fish or chicken bones and corn chips that may impale the esophageal wall leading to eventual leakage.

Caustic Burns

Caustic burns of the esophagus occur from intentional or accidental ingestion of acid or alkali. There are two peaks of incidence: 1 to 5 years of age, when ingestion is usually of a small amount of material and accidental, and in the teens and 20s, when larger quantities are ingested during suicide attempts. Symptoms include hematemesis, respiratory distress, vomiting, drooling, or the presence of oropharyngeal lesions on physical examination.[157] Perforation usually occurs during the latent granulation stage of the disease, approximately 4 to 14 days after ingestion.

The liquefaction necrosis classically resulting from strong alkali burns (pH >12) is more likely to cause esophageal perforation than the coagulation necrosis resulting from strong acid burns (pH <2). Individuals ingesting alkali substances with a pH less than 11.5 rarely sustain injuries more serious than superficial mucosal burns. Acid ingestions cause damage more frequently in the stomach than in the esophagus.[157]

In treating a patient who has ingested a caustic substance, decontamination should involve only the rinsing of the mouth. Dilution of the substance with milk or water has been suggested; however, further liquid ingestion should be avoided if there is suspicion of perforation. Emesis, gastric lavage, and charcoal should be avoided.[154]

Endoscopy within the first 6 to 18 hours may be used to determine the extent of the injury and to guide therapy. Antibiotics are reserved for patients with evidence of perforation, and steroids are suggested by some authors if the burns are circumferential or transmural. Other authors have shown that in the setting of large alkali ingestions, corticosteroids not only did not prevent the formation of esophageal stenosis but also increased the risk of other complications.[157]

Although admission after significant ingestion is the rule, some authors suggest that in the setting of accidental ingestion in children and in the absence of symptoms, endoscopy and admission may not be indicated.[158,159] Esophagoscopy is commonly undertaken to ascertain the presence or absence of esophageal injury. Advancing the esophagoscope beyond the first burn in the esophagus increases the risk of perforation and is a common iatrogenic cause of esophageal perforation.

Penetrating and Blunt Trauma

Because of its well-protected position posteriorly, esophageal trauma occurs in approximately 5% of patients with injuries to the neck, but only 1% of blunt trauma victims, and it is usually not an isolated injury.[152] Cervical esophageal injuries are the most common because of a lack of protection by the bony thorax, and the trachea is the most common associated site of injury.[152] In some cases, the esophageal injury may be overlooked initially because of the dramatic presentation of a patient with a tracheal injury.

Typical symptoms seen in cervical esophageal injuries include neck pain, dysphagia, cough, voice changes, and hematemesis. Physical findings may include neck tenderness, resistance to flexion, crepitus, or stridor.[152,158] In one large series, the most common life-threatening problem in the ED was compromise of the airway. Most of these cases were handled with rapid sequence intubation, but a significant number (12%) of patients required cricothyroidotomy.[152]

If the patient's condition is stable, a preoperative esophagogram with a water-soluble agent should precede any endoscopy. Although chest and neck radiograph and CT also may be used to diagnose this injury, emergent bedside flexible endoscopy seems

www.ketabpezeshki.com 66485457-66963820

to be the test of choice to confirm negative findings on esophagography (especially in the setting of penetrating trauma).[160] Operative repair is indicated in most of these injuries (>90%) and should be done as quickly as possible to avoid the development of fistulae, mediastinitis, or abscess formation.[158]

Blunt traumatic injuries to the esophagus occur much less often than penetrating injuries. The pathophysiology and prognosis of blunt injuries to the esophagus are similar to those of spontaneous rupture or emesis. In some cases, rupture of the cervical esophagus has been reported in association with cervical spine fracture.[161]

Spontaneous Rupture

Spontaneous esophageal rupture, postemetic rupture, and *Boerhaave's syndrome* are synonymous terms. This esophageal injury is associated with a poor prognosis because the forces required to rupture the esophagus result in almost instantaneous and massive mediastinal contamination. The distal esophagus is the usual site of injury, with a longitudinal tear occurring in the left posterolateral aspect. More than 80% of these injuries occur in middle-aged men who have ingested alcohol and large meals.

In vitro, a tear similar to that seen in cases of Boerhaave's syndrome requires a force of 3 to 6 psi, which may be generated in vivo by gastric pressure caused by the reverse peristalsis (seen with emesis) pushing against a closed cricopharyngeal muscle. The role of preexisting gastrointestinal disease in spontaneous rupture of the esophagus is unclear. Some authors emphasize its importance, whereas others report that 80% of esophageal ruptures occur in a previously normal esophagus.[160] Less pressure is required to perforate a diseased esophagus. Approximately 25% of patients with Boerhaave's syndrome have no history of emesis.[152] Increases in intra-abdominal pressure resulting from blunt trauma, seizures, childbirth, laughing, straining at stool, and heavy lifting have all been reported to cause this injury.

Diagnostic Findings

The diagnosis of esophageal perforation is aided by consideration of clinical circumstances. In patients with classic Boerhaave's syndrome, emesis is followed by severe chest pain, subcutaneous emphysema, and cardiopulmonary collapse. Development of these signs and symptoms after instrumentation of the esophagus or removal of an esophageal foreign body is relatively straightforward. One third of cases of perforated esophagus are atypical, however. Only a careful history and physical examination supplemented by appropriate laboratory and diagnostic studies enable the clinician to diagnose a subtle case at an early stage. In considering any of the diagnoses listed in Box 45-5, a perforated esophagus should also be considered.

Clinical Features

The most reliable symptom of an esophageal injury is pleuritic pain localized along the course of the esophagus that is exacerbated by swallowing or neck flexion (Fig. 45-27). Pain may be located in the epigastrium, substernal area, or back; usually worsens over time; and may migrate from the upper abdomen to the chest. As the infectious process worsens, dyspnea usually ensues.

The early physical signs of an esophageal perforation are sparse. As air and caustic contaminated material move through the esophageal tear into the mediastinum and pleural space, and before any subcutaneous air is palpable at the root of the neck, the mediastinal air may impart a nasal quality to the voice. Mediastinal air may surround the heart and produce a systolic crunching sound (Hamman's crunch). As air and fluid move into the pleural space, signs of a hydropneumothorax or an empyema may develop. Eventually the air travels into the subcutaneous tissues, dissecting into the neck, where subcutaneous emphysema may first become evident. This classic sign is present in only approximately 60% of patients, however, and in the absence of a tracheal injury, it may occur in only 30%.[162] As the infectious and inflammatory process advances, the patient's general appearance and vital signs begin to manifest the signs of cardiopulmonary collapse and sepsis with fever, cyanosis, hypotension, anuria, and eventually death.

Box 45-5 Clinical Conditions That May Mimic Esophageal Perforation

1. Spontaneous pneumomediastinum
2. Aortic aneurysm (thoracic)
3. Pulmonary embolus
4. Perforated peptic ulcer
5. Myocardial infarction
6. Pancreatitis
7. Mesenteric thrombosis
8. Cholecystitis
9. Pneumonia

Diagnostic Strategies

Laboratory studies provide largely nonspecific findings. If tested, the pleural effusion of esophageal perforation may show a high salivary amylase level and a low pH. The radiographic examination usually suggests the diagnosis of an esophageal perforation. The classic chest radiograph findings are as follows:

1. Mediastinal air with or without subcutaneous emphysema
2. Left-sided pleural effusion
3. Pneumothorax
4. Widened mediastinum

Lateral views of the cervical spine may reveal air or fluid in the retropharyngeal area that is characteristic of a cervical esophageal perforation but also is found when perforations in the lower parts of the esophagus release air or fluid that dissects superiorly (Fig. 45-28). Most patients exhibit one or more of these abnormalities at some point in the course of the illness, but radiographic evidence of the perforation may be absent early.

The literature is not conclusive regarding whether insoluble barium contrast medium or water-soluble diatrizoate meglumine (Gastrografin) is the preferred initial study. Gastrografin does not obscure visualization with subsequent endoscopy, and it produces less mediastinal soiling than does barium. It is generally recommended that the initial study use this water-soluble agent; then, if no leak is shown, a barium study may be undertaken to better define the mucosal detail.

Endoscopy, similar to contrast studies, is not an infallible aid in establishing the presence or absence of an esophageal perforation. The size and location of the perforation and the skill of the endoscopist are important factors in the low incidence of false-negative studies.[164] If the accuracy of the endoscopy is in doubt, an esophagogram should be performed. Helical CT with dilute oral contrast has been reported as a safer, faster, and less manpower-intensive diagnostic examination.[165] Some of the abnormalities that may be seen on CT scan include extraluminal air, periesophageal fluid, esophageal thickening, and extraluminal contrast. These CT findings may be the first clue to the correct diagnosis of esophageal perforation.

Management

Early diagnosis can best be accomplished if one is aware of the pathophysiology and clinical settings in which esophageal perforations occur. Time is crucial in minimizing the mortality and morbidity of this condition. If the diagnosis is strongly suggested or confirmed, management should include broad-spectrum

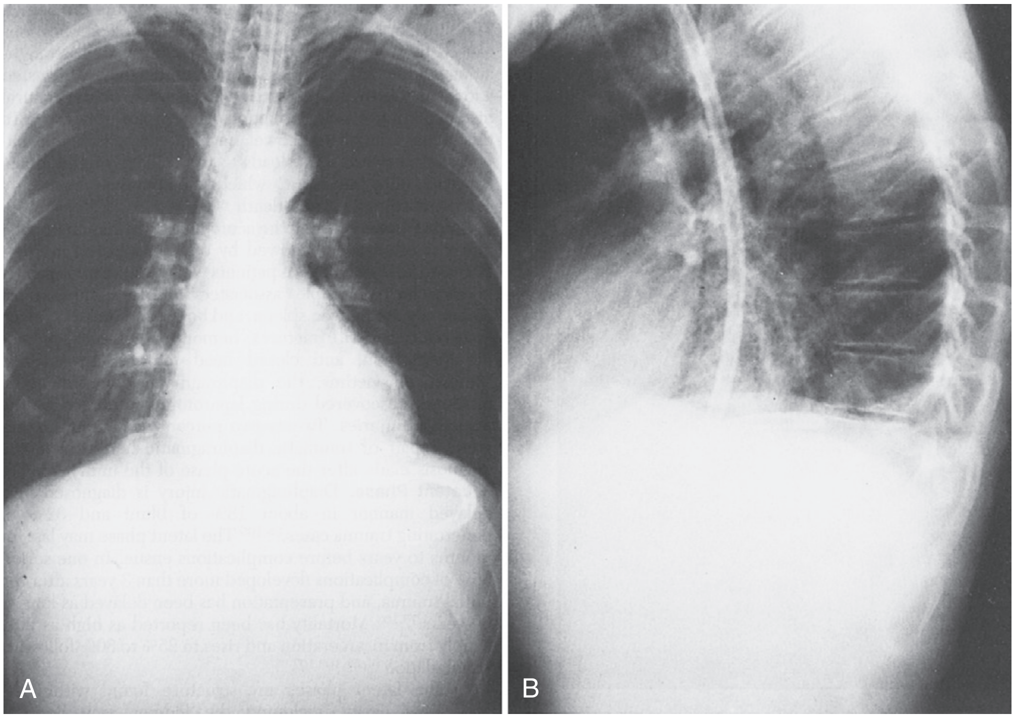

Figure 45-27. **A,** Chest radiograph of a 36-year-old man with acute onset of pleuritic chest pain after forceful vomiting. **B,** Chest radiograph shows mediastinal and subcutaneous air typical of ruptured esophagus. Mediastinum is not yet widened, and there is no soilage of the pleural cavity.

Figure 45-28. Lateral view of the cervical spine revealing air in the retropharyngeal area (*arrow*).

antibiotics (covering oral flora), volume replacement, and airway maintenance.[163-165] An emergency surgical consultation should be obtained because prognosis worsens as time passes, with mortality almost doubling in the first 12 hours.

Although operative therapy is standard, nonoperative therapy is an option for patients with well-contained perforations, with minimal mediastinal involvement, and without evidence of sepsis.[165] In such cases the patient is placed on nothing-by-mouth (NPO) status for at least 72 hours, broad-spectrum antibiotics are initiated, and usually total parenteral nutrition treatment is begun. The use of nasogastric tubes should be discouraged because they may increase gastroesophageal reflux and worsen the contamination of the mediastinum.[164,165]

KEY CONCEPTS

- Even relatively minor chest wall injuries, such as rib fractures, may result in serious complications in elderly patients and patients with preexisting pulmonary disease.
- Children are more susceptible to pulmonary contusion because of greater compliance of the chest wall.
- Unless there are abnormalities on the initial ECG, there is no need to pursue the diagnosis of myocardial contusion with more sophisticated tests.
- Many patients with myocardial rupture or traumatic aortic rupture survive to reach the hospital and can be salvaged with rapid diagnosis and intervention.
- Pericardial tamponade can be diagnosed accurately before hemodynamic decompensation occurs by standard cardiac ultrasound performed by emergency physicians.
- Chest CT should be considered for patients with mechanisms of injury that raise concern regarding blunt aortic injury even in the presence of normal chest radiographs.
- Injury of the esophagus is relatively common with penetrating trauma of the chest or neck. Because the presentation is initially subtle and the potential complications are severe, the diagnosis of esophageal perforation is actively pursued in cases in which the trajectory of the penetrating wound potentially involves the esophagus.

Chapter 46

Abdominal Trauma

Michael A. Puskarich and John A. Marx

PERSPECTIVE

Background

The management of abdominal trauma should be approached in an organized, vigilant, and knowledgeable manner. Reliance on key clinical features and the timely use of diagnostic procedures tremendously alter morbidity and mortality. Advancements in imaging have helped to decrease missed or delayed diagnoses, yet they remain the most serious pitfalls in the management of abdominal injuries.[1]

Penetrating Abdominal Trauma

Whether by accident or intention, penetrating trauma can result from a wide variety of weapons or instruments, and certain elements of therapy vary accordingly. The management of patients with penetrating trauma has changed dramatically since 1960, when Shaftan introduced the concept of selective laparotomy and serial observations.[2] Before that time, surgery was mandatory. The careful integration of physical examination and certain diagnostic procedures, notably local wound exploration (LWE), ultrasonography, computed tomography (CT), laparoscopy, and in rare instances, diagnostic peritoneal lavage (DPL), now provides the emergency physician and trauma surgeon with an accurate means of determining whether laparotomy should be undertaken. The approach varies according to the clinical status of the patient, the instrument responsible for injury, and the site of penetration. Nonoperative management has gained favor predominantly for stab wounds, though also for carefully selected gunshot wounds (GSWs), with the intent to reduce the incidence of and morbidity from nontherapeutic laparotomies.[3,4]

Blunt Abdominal Trauma

Blunt trauma to the abdomen is a supreme challenge to the emergency specialist's clinical acumen. Historical data may be incomplete, absent, or presumptive. The symptoms and signs can be unreliable and obfuscated by head injury, alcohol, or other toxins. The likelihood of extra-abdominal systems trauma adds further complexity, underscoring the need for a carefully organized approach.

Epidemiology

Blunt injuries carry a greater risk of mortality than penetrating injuries because they are more difficult to diagnose and are commonly associated with severe trauma to multiple intraperitoneal organs and extra-abdominal systems.

Penetrating Abdominal Trauma

Wounds from stabbing implements occur nearly three times more often than wounds from firearms, but the latter have a significantly greater mortality rate and are responsible for 90% of penetrating trauma mortality.[5] The small intestine, colon, and liver are, successively, the most likely organs to sustain injury after penetrating trauma.[5] The highest risk of death from penetrating abdominal injury occurs among African Americans in the 15- to 34-year-old age range, followed by Hispanic persons in that same age group. The rate for non-Hispanic whites is greatest at 75 years of age and older. The predominant intent is homicide among African Americans and suicide among non-Hispanic whites.[6]

The use of firearms in the United States contributes heavily to the morbidity and mortality of trauma. The current U.S. civilian population is the most heavily armed in history. Over 42 million U.S. households have firearms, and there are more than 57 million gun owners.[7] The number of homicides committed with firearms exceeds the number of homicides resulting from all other forms of violence combined. More than 850,000 American civilians were killed by bullets in the 20th century, and mortality from GSWs accounts for 12 per 100,000 deaths in urban areas.[8]

Blunt Abdominal Trauma

The spleen is the organ most often injured, and in nearly two thirds of these cases it is the only damaged intraperitoneal structure. The liver is the second most commonly injured intra-abdominal organ, and the intestine is the most likely hollow viscus to be damaged.

The automobile is the major cause of blunt abdominal trauma (BAT). Motor vehicle collisions (MVCs) and auto-pedestrian crashes have been cited as causes in 50 to 75% of cases, blows to the abdomen in approximately 15% of cases, and falls in 6 to 9%.[9]

Pediatrics

Each year in this country, trauma results in approximately 22,000 deaths and accounts for $160 billion of health care expenditures for children to the age of 16 years. Nearly 13% of children admitted to pediatric trauma centers are proven to have abdominal injury, and this category follows only head, neck, and thoracic trauma as the cause of injury-related death.[10] Blunt mechanism causes approximately 85% of pediatric injury, although penetrating violence is becoming a greater concern. As is true with adults, MVCs are responsible for most of the morbidity and mortality in cases of trauma in children.[8] Auto-pedestrian accidents and falls out of cars cause a significant percentage of these injuries.

www.ketabpezeshki.com 66485457-66963820

Child abuse continues to gain attention, and deservedly so. It is both common and extremely harmful. Soft tissue, skeletal, and intracranial injuries are most likely, but abdominal injuries occur occasionally and are second only to head injuries as the cause of death. Children in the preverbal stage, generally those younger than 2 years of age, are at greatest risk. The history of trauma is extremely difficult to obtain because of the inability or fear of the child to communicate and the reluctance of parents to divulge information. Injuries inconsistent with the history provided or not in keeping with the child's level of physical maturity should alert the physician to the possibility of child abuse.

PRINCIPLES OF DISEASE

Anatomy and Physiology

The abdominal cavity and its contents can be reached not only through the anterior abdominal wall and lower chest but also through the flank, back, and buttocks. Missiles can also lodge intraperitoneally after traversing proximal extremities. The *anterior abdomen* is defined as that region between the anterior axillary lines from the anterior costal margins to the groin creases. The *low chest* begins at the nipple line or fourth intercostal space anteriorly and the inferior scapular tip or seventh intercostal space posteriorly, and then extends down to the inferior costal margins. The *flank* is between the anterior and posterior axillary lines bilaterally from the inferior scapular tip to the iliac crest. The *back* is between the posterior axillary lines, beginning at the inferior scapular tip and extending down to the iliac crest. The intraperitoneal cavity is vulnerable when penetration occurs as high as the fourth intercostal space anteriorly and the sixth or seventh laterally and posteriorly because the diaphragm can ascend to this level during expiration. Likewise, simultaneous thoracic abdominal penetration has been found in 20 to 40% of cases of abdominal thoracic trauma.[11] Scrutiny of entrance and exit sites, as well as wound tracts, is imperative.

Pathophysiology

Penetrating Abdominal Trauma

The instruments responsible for penetrating injuries of the abdomen are varied. Knives, handguns, rifles, and shotguns are at the fore, but certain impalement injuries caused by fences, stakes, or similar objects can be treated as stab wounds. Likewise, various propelled missiles from lawn mowers, chain saws, and other machinery or resulting from violent weather should be managed as GSWs.

Fragmentation injuries produced by grenades and bombs are rare in this country, but industrial explosions can produce similar injuries, which are best categorized as shotgun-type wounds. BAT from blast effect can coexist in this setting. With more widespread terrorism, an increased number of these injuries can be predicted.

The liver, followed by the small bowel, is the organ most often damaged by stab wounds, in keeping with the surface area each of these structures presents.[4] The frequency of organ injury caused by GSWs is greatest for small bowel, followed by the colon and then the liver.[5] Typically, multiple organ injuries are sustained, notably perforations to bowel. This same pattern is seen in the pediatric patient.

Stab Wounds. Knives are not the sole implements used in stabbings. Ice picks, pens, coat hangers, screwdrivers, and broken bottles, to name a few, have been used by assailants. Stab wounds of the abdomen occur most commonly in the upper quadrants, the left more commonly than the right. They are multiple in 20% of cases and involve the chest in up to 10% of cases. Most stab wounds do not cause an intraperitoneal injury, and the incidence varies with the direction of entry into the peritoneal cavity. Anterior stab wounds penetrate the peritoneum in approximately 70% of cases but inflict a visceral injury in only half of these.[4] Left lower chest wounds are associated with a 17% incidence of intraperitoneal damage in addition to the expected high rate of thoracic and diaphragmatic injuries. Right lower chest wounds have a much lower incidence of 0% to 4%.[12] Abdominal entries from the flank and back have reported incidences of up to 44% and 15%, respectively.[13,14] The organ injured cannot be well predicted by the site of entry in the abdominal wall. The liver and spleen are the viscera most commonly damaged in cases of back and flank wounds.

Gunshot Wounds—Ballistics. The science of ballistics is complex, but a few basic principles are helpful in understanding the pathophysiologic processes of these injuries. The magnitude of the injury is proportional to the amount of kinetic energy imparted by the bullet to the victim, according to the following equation:

$$E = \frac{7000mv^2}{2g}$$

where E is the kinetic energy (in foot-pounds), m is the mass of the bullet, v is the velocity of the bullet (in ft/s), and g is gravitational acceleration (in ft/s). In other words, the degree of injury depends on the mass of the bullet and the square of its velocity.[15] Additional factors that affect injury created by a missile include the resistance and viscoelastic properties of the tissue through which it passes, as well as the stability of the missile in this medium. Missile velocities are categorized as low (slower than 1100 ft/s), medium (1100-2000 ft/s), and high (faster than 2000-2500 ft/s); the impact velocity is the most important determinant of wounding capability. The impact velocity depends on the distance between the firearm and the victim, the muzzle velocity, and various characteristics of the missile. At medium and high velocities, the missile has an explosive effect and creates a temporary passage in the tissue along its course. The size of this passage is directly proportional to the specific gravity of the penetrated tissue. This sudden formation of a tract displaces nearby organs and vascular structures, and bone and viscera may be fractured or torn without being directly struck by the missile. Several cases of an intraperitoneal injury caused by a bullet that remained extraperitoneal throughout its entire course have been reported.[16] Solid viscera, such as the liver and spleen, are more vulnerable to this effect.

High-Velocity Missiles. Wounds from high-velocity missiles involve additional problems. First, external contaminants tend to be dragged into the wound. Second, the closure of the tract immediately after the bullet's passage may lead to an underestimation of tissue damage. Finally, high-velocity bullets can fragment internally. In fact, a missile at any velocity can fragment after contact with bone and cause additional multiple trajectories and injuries. Civilian wounds have usually resulted from low-velocity handguns, but unfortunately a trend toward more destructive weapons, such as the .38 and .357, may be occurring.

Shotgun Wounds. The shotgun was designed to strike a small, fast-moving target at close range. Because of the ballistic shape of the individual pellets, a rapid falloff in velocity occurs, making this weapon ineffective in producing severe wounds at long distances. An initial muzzle velocity of 1300 ft/s drops to 950 ft/s within 20 yards, a decrease of 25%. At close range (<15 yards), however, the shotgun is extremely lethal.

The kinetic energy imparted to the victim depends on the pellet's size, the number of striking pellets, the type and amount of powder, and the barrel choke (constriction). The most important variable is the distance between the shotgun and the victim. At a distance of 10 yards, 19% of the pellets cluster in a 9-inch diameter

www.ketabpezeshki.com 66485457-66963820

circle if fired from a full choke (maximum constriction) barrel. At a distance of 20 yards, the circle is approximately double that diameter. Because the kinetic energy is proportional to the square of the velocity, a 25% loss of velocity at 20 yards results in a significant decrease in the damage produced by the blast.

Shotgun wounds have been previously classified in three groups according to the range and pattern of distribution. More recently, classification has been according to the pattern of injury on the victim. Based on distance from the weapon to the victim, type I wounds involve a long range (>7 yards) and a penetration of subcutaneous tissue and deep fascia only. Type II wounds occur at a distance of 3 to 7 yards and may create a large number of perforated structures. Type III wounds occur at point-blank range (<3 yards) and involve a massive destruction of tissue. When categorized by pattern, type I wounds produce a spread greater than 25 cm in diameter; type II, 10 to 25 cm in diameter; and type III, less than 10 cm in diameter.[17] The tissue damage is proportional to the specific gravity and inversely proportional to the elastic properties of the affected organ. Thus the liver is more vulnerable than the lungs to this injury. Close-range shotgun wounds, in addition to the shot, force external contaminants (e.g., clothing and parts of the shell wadding) into the wounds. Type III wounds carry a substantial mortality risk.

Blunt Abdominal Trauma

Several pathophysiologic mechanisms have been described to occur in patients with BAT. First, sudden and pronounced rises in intra-abdominal pressures created by outward forces can cause rupture or burst injury of a hollow organ. Lap-belt–only restraints produce such a mechanism. Second, the compression of abdominal viscera between the applied force to the anterior wall and the posterior thoracic cage or vertebral column produces a crushing effect. Solid viscera are especially vulnerable to this injury, helping account for the high incidence of liver and spleen injuries in cases of BAT. Crush injuries are more likely to occur with the lax abdominal wall characteristic of elderly and alcoholic patients. Finally, acceleration and deceleration forces affecting both hollow and solid viscera cause organs and vascular pedicles to shear, especially at relatively fixed points of attachment.

Seatbelt Injuries. Unrestrained front and rear seat passengers are at unequivocally greater risk of intra-abdominal injury than their restrained counterparts.[18] The three-point shoulder-lap belt is the most effective restraining system and is associated with the lowest incidence of abdominal injuries, compared with older systems. However, abdominal injuries are still ascribed to combined shoulder-lap and lap-belt systems. The shoulder belt component can lead to right-sided and left-sided rib fractures for the driver and front seat passenger, respectively, with potential for injury to underlying abdominal viscera. Improper underarm usage of the shoulder belt increases compressive forces to the upper abdomen, particularly in the event of a front-end crash.

Injuries resulting from solitary lap belts are most often to the abdomen. This is true of nearly half the injuries caused by lap belts. The pathogenesis is usually the compression of bowel between the belt and the vertebral column. Occasionally, an acute, short, closed-loop obstruction occurs along with perforation secondary to the sudden generation of high intraluminal pressures. The resultant injury is primarily a contusion or perforation of the intestines or a tear of the mesentery.

Clinically, two symptom patterns emerge. Approximately one fourth of these patients develop evidence of a hemoperitoneum secondary to mesenteric lacerations. In the remainder, the intestinal injury most commonly involves the jejunum, and the initial signs and symptoms are often absent or considered insignificant. Subsequent delays in diagnosis of up to 8 weeks have rarely been reported. The "seatbelt sign," contusion or abrasion across the lower abdomen, is found in less than one third of patients with abdominal injuries caused by lap belts. Its presence, however, is highly correlated with intraperitoneal pathologic lesions.[19] Rupture of the diaphragm can also occur. Rare cases of acute abdominal aortic dissection with incomplete or complete occlusion have also been described, and injuries to the lumbar spine are not uncommon.[20]

Iatrogenic Injuries. Although well intentioned, diagnostic and therapeutic efforts in patient care are not risk-free. Abdominal injuries may be sequelae of various medical procedures and in certain instances not only are extremely difficult to recognize but may contribute to or cause pronounced morbidity or death. Numerous procedures may cause an iatrogenic injury.

Artificial ventilation can lead to gastric distention, particularly in children. Besides compromising ventilation and increasing the risk of vomiting and aspiration, a significant distention may lead to an esophageal or gastric laceration and perforation. These may occur with bag-mask ventilations, an inadvertent esophageal intubation with a nasotracheal or endotracheal tube, or the mistaken connection of the nasogastric tube to oxygen rather than suction. Esophageal, gastroesophageal junction, and gastric lacerations are evidenced by bloody emesis or nasogastric return. If a gastric perforation occurs and positive-pressure breathing is maintained, a tension pneumoperitoneum or abdominal compartment syndrome may ensue with inferior vena cava compression and decreased cardiac output. External cardiac compressions have produced splenic, hepatic, and gastric injuries. Manual thrusts to clear an airway obstruction, as taught in basic life support courses, and the Heimlich maneuver have caused rib fractures with lacerations and the rupture of abdominal viscera. In cases of a cardiac arrest, these injuries may be occult but life-threatening. If hypotension occurs after cardiopulmonary resuscitation, an abdominal injury and hemorrhage are considered along with cardiogenic shock.[21]

Tube thoracostomy has resulted in injury to the liver and spleen. These injuries may result from an unrecognized elevation of the diaphragm on the side of the thoracostomy or the placement of the tube too low in the chest, with resulting intra-abdominal penetration. Peritoneal lavage, paracentesis, and peritoneal dialysis have caused a series of complications, especially vascular penetration and bowel perforation. Signs of blood loss from a hemoperitoneum in the former case and peritonitis in the latter will evolve.

A liver biopsy can lead to a hemoperitoneum or hemobilia. Endoscopic procedures of the bowel may cause a hollow viscus perforation and peritonitis, particularly when a biopsy is performed, although they can result from rapid retraction of the endoscope without biopsy, as well.[22] Peritoneoscopy has been reported to cause small bowel perforations and iliac vessel lacerations. Barium enemas have an extremely low incidence of perforation but can be another cause of unexplained peritonitis and pneumoperitoneum.

Pediatrics. Congenital anomalies and intra-abdominal neoplasms may be first discovered after a history of blunt trauma. Coagulopathies (e.g., hemophilia) can contribute to the pathologic condition and complicate therapy after apparent minor trauma to the abdomen.

A child's abdomen has poorly developed musculature and a relatively smaller anteroposterior diameter. These factors increase the vulnerability of abdominal contents to compression between a blunt anterior force and the solid posterior vertebrae. The rib cage is extremely compliant in children and less prone to fractures but nonetheless provides only partial protection against splenic and hepatic injuries. Finally, the bladder is less protected by the pelvis in children, exposing it to greater risk of injury.

The liver, spleen, and kidney are the organs most commonly damaged by blunt mechanism of all varieties, and the incidence of injury for each of these three solid viscera is roughly the same. Gastrointestinal tract perforation is not uncommon with blunt

www.ketabpezeshki.com 66485457-66963820

trauma, and these injuries may be isolated. In cases of nonaccidental trauma, those injuries seen most commonly are duodenal and small bowel hematomas and perforations, pancreatic contusions, lacerations and pseudocysts, lacerations and rupture of the liver and spleen, and lacerations of mesenteric vessels.

CLINICAL FEATURES

History

The patient's history may be unobtainable, elusive, or temporarily deferred while resuscitative measures are carried out. When the situation permits and a reliable source is available, certain information is valuable.

The patient's ability to relate the course of events may be compromised by head or spinal cord injury, alcohol intoxication, developmental delay, psychiatric illness, and any number of toxins. At times, the trauma may have preceded the onset of symptoms by days or weeks and may have been forgotten or considered trivial by the patient. Witnesses at the scene, particularly paramedical personnel, often provide the most reliable data.

Knowledge of substance exposure or events that could interfere with the clinical evaluation of the patient is helpful. Alcohol or drug use, a head or spinal cord injury, and psychiatric problems are the most common among these factors. Appreciation of comorbid medical conditions, particularly cardiovascular disease and coagulopathies, optimizes fluid and blood component therapy. Finally, when a prehospital care team or transferring hospital is involved, the vital signs, physical assessment, prehospital course, and response to therapy should be obtained. Clinical records and laboratory and radiologic studies obtained at an outlying hospital should be carefully reviewed. The symptomatology in cases of abdominal trauma is twofold. Volume loss may produce orthostatic or frank dizziness, light-headedness, and confusion. A hematic, infectious, acidic, or enzymatic irritation of the peritoneum produces pain. The pain may be clearly present at the outset or delayed for hours to days.

The patient's communication may be dulled or ineffectual, or the subjective sensation of pain may be impaired by a spinal cord injury or an underlying medical problem such as diabetes. Occasionally, intense, competing pain at another body site dominates and distracts both the patient and physician away from the abdomen. Abdominal pain can be localized, as it sometimes is in the left upper quadrant with a splenic injury, or diffuse, as in septic peritonitis subsequent to bowel perforation. Referred pain to the right and left shoulder tips or neck can occur with hemoperitoneum, particularly when the patient has been in the Trendelenburg position, allowing the blood to irritate the diaphragm; this most often occurs with hepatic and splenic injuries. Pain referred to the testicle is compatible with a retroperitoneal injury and is seen most commonly with urogenital and duodenal trauma.

Nausea and vomiting can accompany peritoneal irritation or hypovolemia. These can also be caused by an obstruction, as can occur with a duodenal hematoma. Dyspnea sometimes occurs with gastric distention or diaphragmatic irritation or when abdominal contents herniate into the chest, impairing respiratory dynamics.

Penetrating Abdominal Trauma

Stab Wounds. It is helpful to obtain information regarding the mode of injury from the patient, paramedic, or witnesses. The number of stabs inflicted, type and size of the instrument, posture of the victim relative to the direction of assault, estimated blood loss at the scene, time of injury, and response to fluids should be sought. However, a significant proportion of victims of stab wounds are found under the influence of alcohol or another drug. This state can make obtaining an accurate history a futile effort and further compromises the validity of symptoms and signs.

Gunshot Wounds. As initial stabilization measures are instituted in the emergency department, the emergency physician can elicit certain facts that can contribute greatly to the evaluation of the patient. These include the weapon used, its distance from the victim when shot, the position of the victim in relationship to the weapon when fired, the suspected number of shots, the blood loss at the scene, the amount and type of field fluids administered, and the vital signs during the prehospital course.

Blunt Abdominal Trauma

With blunt injuries, specifically those resulting from vehicular trauma, inquiries should be made regarding the extent of damage to the car; the patient's location within the car; whether the patient struck the steering wheel; whether seat belts were used and, if so, what type; and whether front or side air bags were deployed. The magnitude of injury to pedestrians varies with the speed and size of the striking vehicle. A triad of injuries to the torso, cranium, and lower aspect of the lower extremity has been well described, and pathologic lesions discovered in two of these sites should prompt careful attention to the third. Motorcycle crashes can be placed in one of four categories: frontal, lateral or angular, ejection, or "laying the bike down." Different pathologic lesions can be projected based on the offending mechanism.

Pediatrics

Assessment and management of abdominal injuries in children are based on the same principles as in adults. The symptoms and signs are similar and in alert, cooperative patients are valuable. Age-related difficulties in communication, fear-induced uncooperative behavior, or a concomitant head injury, however, make the clinical examination less reliable. In cases of unexplained abdominal tenderness or peritonitis, it is important to inquire about vaginal bleeding or discharge and rectal bleeding and to examine the rectum and vagina for foreign bodies. Such objects may be inserted by inquisitive children or by adults during acts of child molestation.

Physical Examination

Abdominal trauma provokes a wide spectrum of presentations that range from seemingly insignificant symptoms and signs to severe shock and coma. Evidence of abdominal tenderness, peritoneal irritation, gastrointestinal hemorrhage, and hypovolemia not attributable to extra-abdominal causes represents most of the signs suggestive of an intraperitoneal injury. These signs may be initially absent or obscure but may emerge during serial examinations.

The physical examination of a hemodynamically unstable patient is performed coincident with therapy, but care and thoroughness are not precluded by these circumstances. When an obvious intracranial, thoracic, or orthopedic injury is present, abdominal symptoms or findings may be obscured, and abdominal injury should be considered. Chest trauma itself is a risk factor for coincident intraperitoneal pathology. This is particularly true in cases of suspected multiple blunt trauma accompanied by a head injury, coma, or obtunded mental status resulting from drugs or alcohol.

The abdomen, then, should neither be ignored nor be the sole focus of the evaluation. All of the patient's clothing should be removed, and a careful inspection of the patient's body should be conducted, to include the scalp, perineum, skin folds, and beneath the hair. Wounds from penetrating trauma can be exceptionally small, difficult to find, and yet lethal.

www.ketabpezeshki.com 66485457-66963820

Hypotension in the acute stage results from hemorrhage that is most often from a solid visceral or vascular injury. Traumatic pancreatitis may produce significant third-space fluid loss, but hours to days are usually required for this to appear, and shock is an uncommon presentation.[23] When hypotension accompanies significant multiple blunt trauma and is unexplained, one should assume the presence of intraperitoneal hemorrhage until it is excluded. However, a known extra-abdominal source of hemorrhage does not mitigate the need to evaluate the peritoneal cavity. A head injury alone does not explain shock except in cases of profound head injury or in the very small infant, in whom traumatic intracranial or extracranial (e.g., cephalohematoma) blood loss may be proportionally substantial.[24]

In cases of penetrating trauma, inspecting the abdomen for entrance and exit wounds may help determine the path of injury. Distention can occur as a result of pneumoperitoneum, gastric dilation, or ileus produced by peritoneal irritation. An ecchymotic discoloration of the flanks (Gray-Turner sign) or umbilicus (Cullen's sign) indicates retroperitoneal hemorrhage, but these signs are usually delayed for 12 hours to several days. Abdominal contusions can result from various implements, and when caused by lap-seat belts, they herald abdominal injuries in one third of cases.

Markedly decreased or absent bowel sounds have traditionally been considered one of the more reliable clinical parameters of intraperitoneal injuries. However, the presence of audible peristalsis, although uncommon, does not rule out ileus or serious injury. In such instances, coexisting electrolyte disturbances or thoracolumbar vertebral body or transverse process fractures may be responsible for the ileus.

Palpation elicits local or generalized tenderness in approximately 90% of alert patients with an intra-abdominal visceral injury. Local and generalized rebound tenderness and rigidity can be signs of peritoneal irritation and occur less commonly. These signs lack specificity, however, and can be found with lower rib fractures and contusions of the thoracoabdominal wall. These findings or, more important, their absence, are more reliable in alert patients. However, false-positive and false-negative abdominal manifestations have been well demonstrated even in conscious, responsive patients.[25,26]

Rarely, encapsulated bleeding into regions walled off by blood clots or adhesions can form palpable intra-abdominal masses; these usually appear at least several hours later. Severe contusions of the abdominal wall can cause tenderness and voluntary guarding that is localized and usually exacerbated by use of the affected muscle. A palpated mass can represent a rectus hematoma or ventral hernia.

A rectal examination rarely reveals blood or subcutaneous emphysema, but the presence of either is highly correlated with abdominal injuries. The rectal examination is now considered less helpful than clinical indicators such as blood at the meatus or scrotal hematoma in urethral injuries, or evidence of paralysis. The rectal examination can be eliminated or deferred in many patients, as the clinical indicators noted earlier appear to be more sensitive than the rectal examination.[27-29] Notable exceptions may include suspected cauda equina syndrome or penetrating trauma to the perirectal area.

In patients who are intubated, who have a distended abdomen, or in whom there is a high concern for stomach or duodenal injury, a nasogastric tube should be placed in the absence of severe maxillofacial trauma to decompress the abdomen, decrease the likelihood of aspiration, and determine whether blood is present. Caution is advised with placement of nasogastric tubes when a cribriform plate fracture or unstable midface fractures are suspected, as rare cases of intracranial insertion have been reported. Foley catheters are useful in unstable patients for following renal output and rapidly obtaining urine samples to search for blood, myoglobin, and toxins.

Thus a number of signs are valuable in assessing the patient with abdominal trauma. Although the presence of physical findings makes intraperitoneal injury more likely, their absence does not preclude serious pathology, and none is exclusively diagnostic of a specific injury. Extensive observation and the use of certain laboratory procedures greatly help prevent erroneous or missed diagnoses.

Penetrating Abdominal Trauma

Stab Wounds. Serial physical examinations performed by the same observer are gaining acceptance in certain centers where these have been found useful, particularly with patients who are alert, communicative, and neurologically intact. The presence of intoxicants does not necessarily preclude reliance on examination but may undermine its value.[30] In other series, patients with impressive physical findings after penetrating trauma to the abdomen have undergone exploratory laparotomy, with negative results in 14 to 28% of cases.[31] Moreover, up to one third of patients with significant intra-abdominal injuries have no suggestive physical signs, particularly when a retroperitoneal injury has occurred.[32] Therefore serial clinical evaluations typically involve physical examinations to include trending of vital signs, laboratory testing including serial hemoglobin measurement, and repeated focused assessment with sonography in trauma (FAST) examinations.

Gunshot Wounds. As with blunt or other modes of penetrating trauma, there is dispute regarding the value of the physical examination of patients with abdominal GSWs. In various series, 20% of patients with a documented intraperitoneal injury had no peritoneal signs before exploration.[32] Moreover, objective physical findings suggestive of intra-abdominal damage have been misleading and falsely positive in 15% of patients in whom laparotomy revealed no injury. Other authors contend that selective management can be undertaken safely when physical examination is the fundamental evaluative measure.[30]

Blunt Abdominal Trauma

Overall, the accuracy of the physical examination in patients with BAT is 55 to 65%.[25] The initial presentation may be exceptionally benign in cases of blunt intra-abdominal injury. The most reliable symptoms and signs in alert patients are pain, tenderness, and peritoneal findings, particularly when risk factors for abdominal injury are present. When altered sensorium intercedes, the physical signs become less reliable. Frequent evaluations by the same examiner are indicated even in alert patients, but especially in sensorium-altered patients, particularly as their mental status and sensorium normalize.

DIAGNOSTIC STRATEGIES

Laboratory

Hematologic and chemical values are of limited use in the management of the acutely traumatized patient.[33] They should be considered adjuncts to diagnosis and not substitutes for clinical assessment.

Hematology

Hematocrit. The hematocrit reflects baseline value, extent of and time from hemorrhage, exogenous fluid administration, and endogenous plasma refill. The last of these is a physiologic compensatory shift of extracellular fluid into the intravascular space, the intent of which is to restore the original blood volume. Based

www.ketabpezeshki.com 66485457-66963820

on a study of volunteers sustaining a 10 to 20% blood loss, this restoration proceeds at a rate of only 40 to 90 mL/hr for the first 10 hours and requires 30 to 40 hours for completion.[34] However, patients evidencing hemorrhagic shock with a blood loss of at least 40% demonstrate much faster plasma refill rates, estimated as high as 1500 mL in the first 90 minutes after injury, with significant decreases in hematocrit within this period. Although the hematocrit is an easily acquired measure, it is often a conundrum when viewed in isolation, and serial determinations are more helpful.

White Blood Cell Count. The white blood cell (WBC) count has little discriminatory value in cases of abdominal trauma, particularly its acute phase.[33] The WBC count may be normal or may show a modest leukocytosis (12,000 to 20,000/mm^3 with or without left shift), which can occur in the setting of multisystem trauma as a result of stress-induced demargination in the absence of any intra-abdominal process, or as a result of tissue injury, acute hemorrhage, or peritoneal irritation.

Chemical

Pancreatic Enzymes. Neither serum amylase nor lipase is useful in the evaluation of acute abdominal trauma. Normal levels do not exclude a major pancreatic injury, and elevated values may be caused by any of an assortment of reasons in addition to an injured pancreas. The use of serum amylase isoenzymes has not appreciably improved accuracy. Nontraumatic causes of hyperamylasemia include several diseases and the use of alcohol, opioids, and various other drugs. Amylase or lipase may also be elevated with pancreatic ischemia produced by the systemic hypotension that often accompanies trauma. Clearly, these enzymes are neither highly specific nor sensitive for pancreatic injuries. Elevated or rising levels may indicate damage but in themselves are not conclusive.[35] In these cases, clinical correlation and further investigation are indicated.

Base Deficit. Metabolic acidosis in the setting of trauma can suggest the presence of hemorrhagic shock. This can be witnessed chemically as a decreased serum bicarbonate level, increased base deficit, or elevated serum lactate level. Although normal values do not exclude abdominal injury, substantive abnormalities, such as a base deficit greater than or equal to 6, may be predictive. These findings should be considered in clinical context, because the resolution of the laboratory findings will lag behind the clinical improvement of the patient.

Liver Function Tests. Elevated serum transaminases can result from hepatic trauma but do not distinguish minor contusions from severe injury.[36] Alternatively, these may be symptomatic of alcohol-induced liver damage. Elevated liver transaminase levels may be useful for screening pediatric patients for intentional trauma (see Chapter 38). They may also play a role in pediatric patients in combination with a FAST examination as a screening tool to decrease the use of CT scanning, although serial physical examination is still required.[37]

Toxicology Analysis. Screens for ethanol and drugs are often used in trauma centers. Their utility in the management of abdominal trauma, per se, has not been established, particularly in patients with normal mental status.[38] Positive study findings may prompt the emergency physician to interdict and the patient to decrease the recidivistic use of ethanol or drugs, and physician intervention during this "teaching moment" has been shown to be effective.

Radiology

Resuscitation and initial stabilization measures precede abdominal radiographic studies. Basic plain radiography in the trauma bay is of limited value, although a chest x-ray examination to screen for significant hemothorax or pneumothorax before the patient is transferred to the CT scanner facilitates early stabilization of these injuries. Hemodynamically stable patients who will undergo abdominopelvic CT can forego pelvic radiographs in the trauma bay. Any potential cervical or lower spinal injury is presumed present based on the mechanism of the trauma, the patient's symptoms, and physical examination findings. A portable cross-table radiograph in the trauma bay is insufficient to exclude any such injury. In the hemodynamically stable patient, depending on physical findings and whether the patient is able to convey pain, pelvic radiographs may be deferred to the radiology suite or omitted entirely (see later). In patients whose symptoms and signs demonstrate a likely need for exploratory laparotomy, delay in operation because of radiologic diagnostics is permissible only when the patient has been stabilized and only if studies might aid in determining management. Adequate radiographic detail cannot be achieved in an uncooperative patient. Trained personnel should accompany any patient who has potential to deteriorate precipitously. Moving the patient from the relative security of the trauma resuscitation room to the radiology suite creates increased risk for the patient because of the relative decrement in monitoring and personnel in attendance.

Plain Radiographs

The chest radiograph and anteroposterior pelvic films can be invaluable in some cases of penetrating and blunt trauma, depending on the presentation and results of initial evaluation. Plain abdominal films can demonstrate the location or track of the missile(s) in gunshot and shotgun injury but are of little value in blunt trauma or nonprojectile penetrating trauma, particularly if CT imaging of the abdomen is anticipated. If plain radiography of the abdomen is done, the finding of rib, pelvic, vertebral body, or transverse spinous process fractures in the blunt trauma patient warrants special consideration for nearby visceral damage.

Very small quantities of readily detectable free intraperitoneal air are present in most patients with gastric, duodenal bulb, and colonic perforations but in fewer than one fourth of those with jejunal and ileal perforation. These are seen more readily on CT than plain films. Free intraperitoneal air uncommonly can be generated by mediastinal or pulmonary injury, as well as by barotrauma, and thus its presence is not pathognomonic of hollow viscus perforation. Intraperitoneal air is mobile, and to maximize visualization the patient should be kept in the appropriate upright or decubitus position for 10 to 15 minutes, if this is tolerable, before upright chest or decubitus abdominal radiographs are obtained. In upright films, air is located under the diaphragm or the central tendon of the diaphragm anteriorly. In supine films, air tracks under peritoneal attachments, such as the falciform ligament and urachus, up to the anterior abdominal wall. On films in which the patient is in a lateral decubitus position, air is located in the superior flank and outlines the lateral liver edge (Fig. 46-1). In cases of gastric perforations, air may be limited to the lesser sac. A rupture of a retroperitoneal hollow viscus can be detected by a stippling pattern outlining the duodenum, kidney, or psoas muscle (Fig. 46-2). Extraperitoneal colonic perforations may extravasate air, which outlines the psoas muscle and perinephric region. All of these injuries are much more readily identified and localized on abdominal CT.

Foreign bodies and missiles are easily identified on abdominal films. Therefore their absence without a known exit wound warrants further search of other body cavities (e.g., the chest, upper thighs, buttocks). A ricochet off the spine or pelvis into the chest or proximal extremities can occur. An entry into the vascular system may carry the object toward and into the right side of the heart or peripherally into the arterial tree. It may also find its way into the gastrointestinal tract and either produce obstruction or pass through unnoticed.

Computed Tomography

Over the last 35 years, CT scanning has continued to advance its place among diagnostics for trauma. Evolution to higher multislice helical and spiral scanners has improved resolution and greatly decreased the time required for the scan itself.[39]

Advantages. In most situations, CT scanning has supplanted DPL because of its higher predictive ability for operative lesions and because it is noninvasive. CT scanning can define the injured organ and the extent of the injury. It is most accurate for solid visceral lesions and accurately discerns the presence, source, and approximate quantity of intraperitoneal hemorrhage (Fig. 46-3). It can demonstrate active bleeding from the liver or spleen and can be used to determine whether therapeutic angiographic embolization is indicated.[40] CT scanning also evaluates the retroperitoneum (Fig. 46-4), an area not sampled by DPL, as well as the vertebral column, and can be readily extended above or below the abdomen to visualize the thorax or pelvis.[41] CT scanning also provides definitive evaluation for most possible injuries to the urinary tract, including renal artery injury.[42] It can also detect other vascular hemorrhage and obviate the need for angiography in some patients.[43] CT scanning is particularly helpful in guiding nonoperative management of solid organ damage.[44,45] This includes as-needed follow-up studies of convalescing patients with these injuries. It has also proven effective when incorporated in delayed fashion for patients with decreasing hematocrit, increasing base deficit, or subtle examination changes. By minimizing the incidence of nontherapeutic laparotomies for self-limited injury to the liver or spleen, it decreases morbidity and cost attendant to this operation.[46] Increasingly, trauma centers are using CT with intravenous contrast only, as it has been shown that little additional information is provided by the addition of oral contrast, which delays scanning and may pose an aspiration risk for the patient.[47,48]

Disadvantages. Disadvantages of CT scanning include relative insensitivity for injury of the pancreas, diaphragm, small bowel,

www.ketabpezeshki.com 66485457-66963820

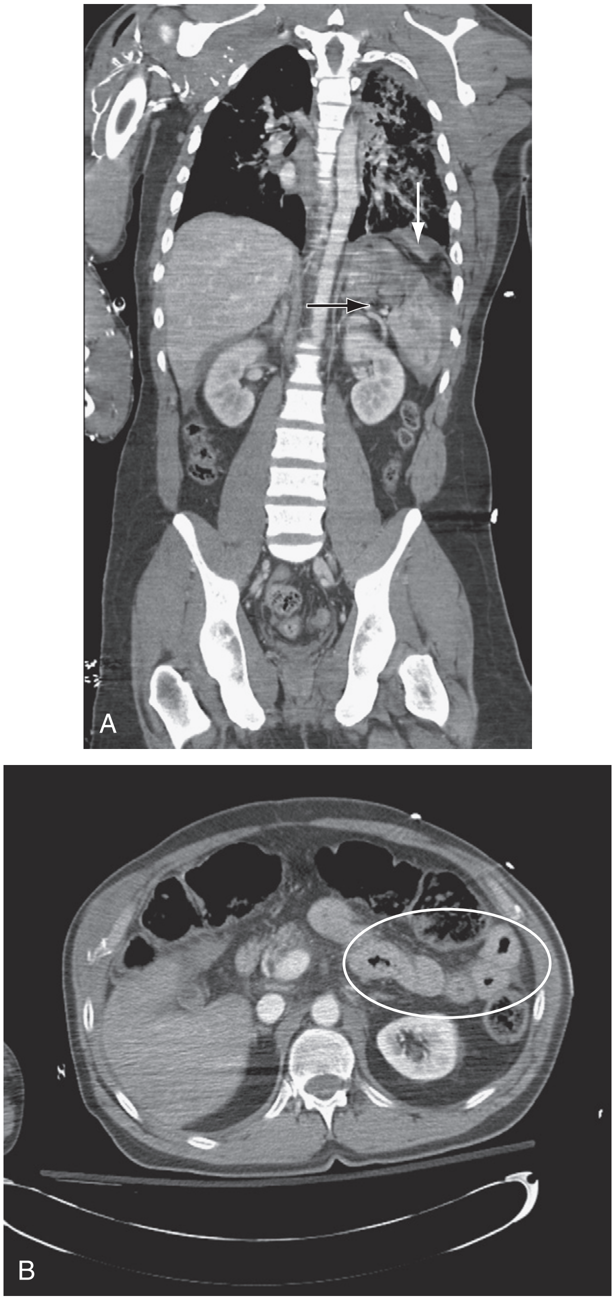

Figure 46-5. **A**, Grade 4 splenic laceration *(black arrow)* with diaphragmatic rupture *(white arrow)*. **B**, Small bowel edema concerning for hollow viscus injury *(encircled)*.

and mesentery, although detection of these injuries is improving[47,48] (Fig. 46-5). The last two are particularly worrisome because isolated coincidental hollow viscus injury in patients with blunt trauma, although uncommon, is not rare, and increased morbidity and death can ensue if diagnosis is missed or the condition goes undetected for a prolonged period. Findings on CT scans, including the suspected quantity of hemoperitoneum or the presence of isolated free fluid, are not able to forecast well the need for operative intervention.[49] Complications can result from intravenous contrast administration or uncommonly from contrast material administered orally. Moreover, oral contrast delivery to opacify bowel is infrequently useful and typically omitted.[47,50] Finally, patients must be temporarily removed from the resuscitation area for the study to be accomplished, which can put the patient at risk in the case of rapid clinical deterioration. However,

Table 46-1 Preferred Site of Diagnostic Peritoneal Lavage

*The stab wound or gunshot wound site should be avoided.

CT scanning remains the cornerstone of diagnosis. In cases with equivocal CT scan results, such as more than physiologic fluid, or a worrisome history and physical examination findings, serial examinations or further diagnostic testing should be strongly considered, including DPL, particularly to evaluate for missed hollow viscus injury (Table 46-1).

Radiation Risk. Increasingly, there is concern regarding the negative long-term effects from exposure to ionizing radiation resulting from medical imaging. Over 62 million CT scans are performed per year in the United States, including over 4 million in children,[51] and the number of scans performed per patient after trauma is increasing.[52] Based on data from survivors of the atomic bombs dropped on Japan and average radiation exposure from various types of CT scans, it has been estimated that 0.4% of all cancers in the United States have been caused by exposure to medical radiation, and that number may be increasing to 1 to 2%. Children are especially at risk, and even a single CT scan may increase the lifetime risk of cancer.[51] Although direct evidence of increased cancer risk from CT scans has not yet been demonstrated, several methods are becoming available to reduce radiation exposure. Some groups have attempted to define decision rules to help avoid unnecessary CT scans in very low-risk patients, though their role in clinical practice has yet to be defined.[37,53,54] For very low-risk, hemodynamically stable patients, special consideration should be given to patients with large numbers of negative CT scans in the past, and observation may be preferable to repeat radiation exposure. Adjustment of scanning techniques for children and body habitus on an institutional level through use of "as low as reasonably achievable" (ALARA) principles, developed in conjunction with the department of radiology, can decrease excessive radiation exposure if CT scanning is clinically indicated. If a patient is to be transferred to another facility, attempts should be made to convey hard copy or digital images to the accepting facility, as CT scans are not infrequently repeated at the receiving hospital.[55] These repeat CT scans are unlikely to change management without a concurrent change in clinical picture.[56] A balance between minimizing radiation exposure and simultaneously minimizing the number of missed injuries is a challenge for the emergency physician evaluating a patient with abdominal trauma.

Technique. The technique for CT scanning is reasonably standardized, but certain conventions are debated. The studies should begin in the low chest and be taken through the pelvis. If chest scanning is also required, a single continuous scan is obtained from the root of the neck to the floor of the pelvis. "Quick look" but less thorough studies are problematic and should be avoided; preliminary reads from the CT control room do not have the added accuracy of reconstituted scans and may therefore miss subtle injuries, such as intimal tears of the thoracic aorta. Most

www.ketabpezeshki.com 66485457-66963820

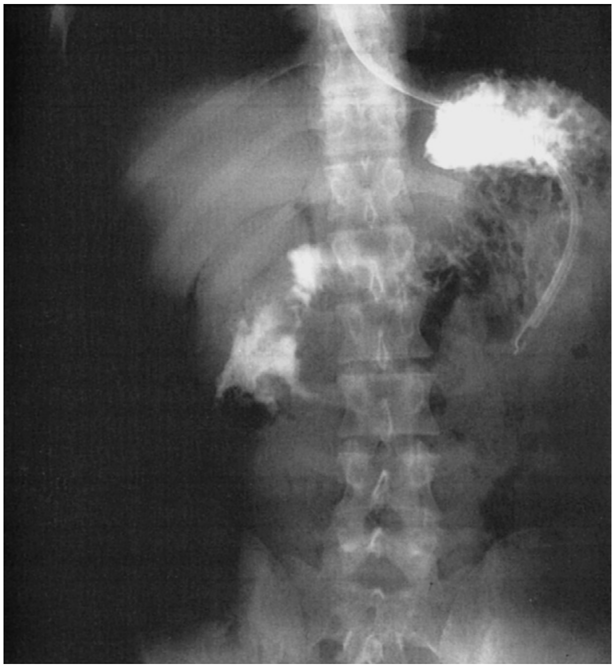

Figure 46-6. Gastrografin study demonstrating rupture of the second portion of the duodenum with extravasation of contrast material.

centers perform enhanced (intravenous contrast) and nonenhanced scans because the latter alone may not demonstrate intraparenchymal hematomas well. Other practitioners believe that the noncontrast portion contributes little other than time to the procedure. In patients who undergo chest and abdominopelvic CTs, reconstituted images can be obtained of the thoracolumbar spine, sparing the need for additional studies and associated ionizing radiation. Except in certain unusual circumstances, single scans through the areas of interest with intravenous contrast only are recommended.

Contrast Studies

Contrast studies with a water-soluble medium (e.g., Gastrografin) can be helpful in cases of suspected gastric, duodenal, and rectal perforations (Fig. 46-6). Barium mixtures should be used to visualize intramural duodenal hematomas.[57] However, a CT scan should be able to discern duodenal hematomas and can distinguish these from perforations.[58]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is usually impractical and sometimes impossible to perform in the acute phase of multiple blunt trauma. Currently, in acutely injured trauma patients, MRI should be reserved for the evaluation of spinal cord injuries and elusive diaphragmatic defects.

Therapeutic Angioembolization

Therapeutic angiography, a time-consuming procedure, is usually reserved for the unstable patient with blunt trauma and pelvic fracture in whom it can be used to embolize bleeding vessels (Fig. 46-7). It can also be a means of staunching solid visceral hemorrhage from blunt trauma, notably of the spleen.[40] Nonoperative management has become standard in management of splenic injuries but is associated with increasing failure rates with increasing grades of injury, up to 44% with the highest-grade injuries. Successful nonoperative management has been demonstrated to

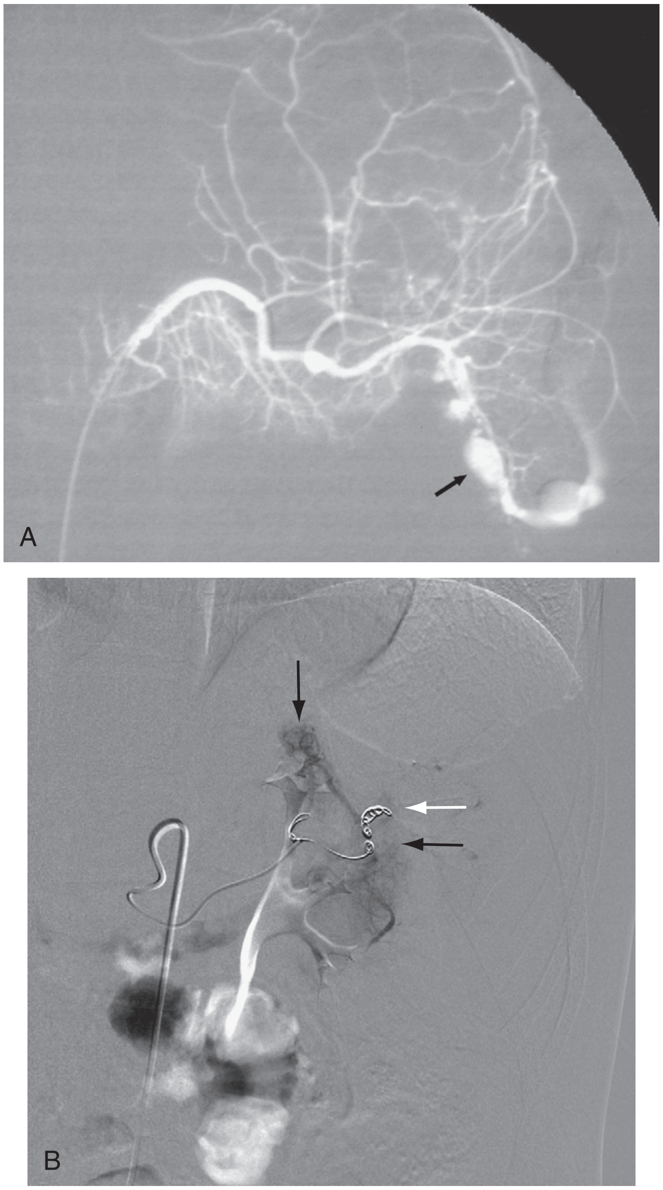

Figure 46-7. A, Angiography of splenic laceration. Note the blush representing active hemorrhage *(black arrow)*. B, Angioembolization of renal laceration. Philadelphia, Elsevier Health Sciences, 835, 2008.)

increase significantly with the use of angioembolization therapy,[59] though higher-grade injuries are still more likely to fail nonoperative management than lower-grade injuries.[60] Angioembolization also may have the added benefit over splenectomy of preserved splenic immunity in many cases, though further data are needed on the topic.[59] The angioembolization catheter should be inserted as close as possible to the hemorrhaging lesion to minimize infarction of viable tissue. Finally, angioembolization also has been used rarely for intraperitoneal and retroperitoneal hemorrhage after trauma by a penetrating mechanism.

Bedside Procedures

Ultrasonography

Ultrasonography's primary role is detecting free intraperitoneal blood after blunt trauma. This is accomplished by a FAST

www.ketabpezeshki.com 66485457-66963820

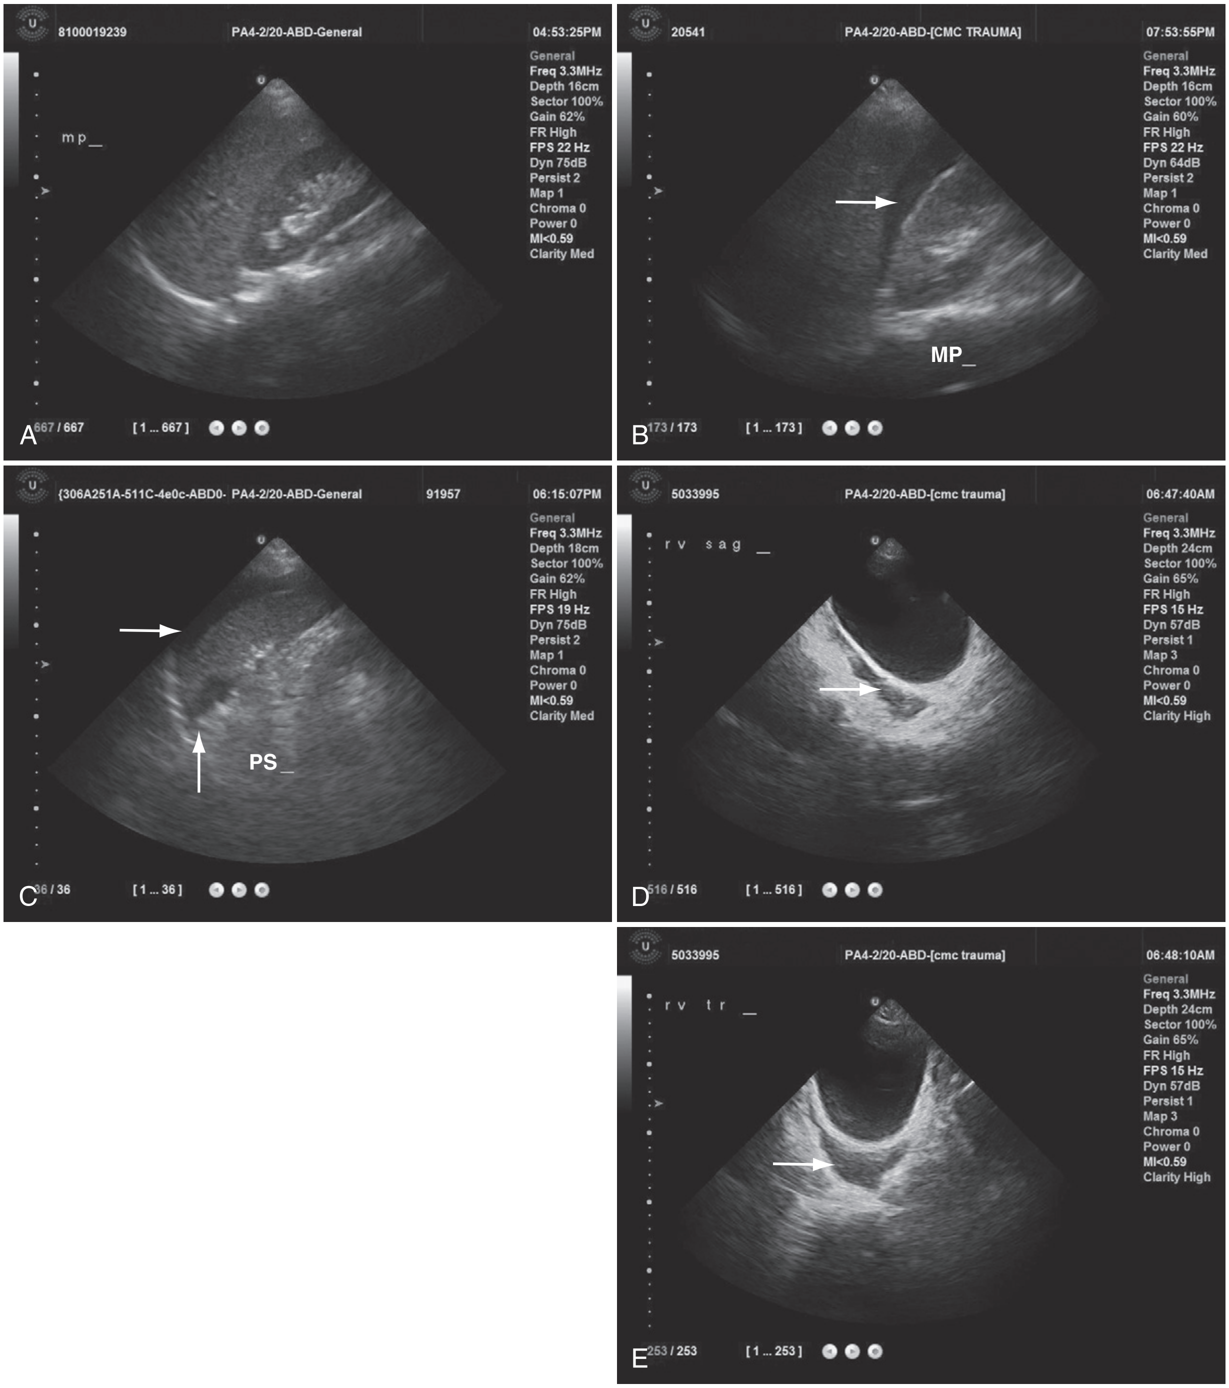

Figure 46-8. **A,** Normal Morrison's pouch view. Note absence of an anechoic stripe, which would represent a fluid collection between the liver and kidney. **B,** Positive Morrison's pouch view. ultrasound examination of Morrison's pouch, the splenorenal recess, and the pouch of Douglas, which are dependent portions of the intraperitoneal cavity where blood is likely to accumulate (Fig. 46-8). Anechoic areas caused by the presence of blood are best visualized when contrasted against solid organs (e.g., liver, spleen, and kidneys). With penetrating mechanisms, an extended FAST (E-FAST) ultrasound adding visualization of the pleura and pericardial and intraperitoneal spaces can also detect pneumothorax, hemothorax, and pericardial tamponade.[61]

Advantages. Ultrasonography carries a host of advantages. It is a portable instrument that can be brought to the bedside in the trauma resuscitation area. Studies of the pericardial, intraperitoneal, and thoracic spaces can be accomplished in less than 5 minutes. FAST ultrasound has a sensitivity in detecting as little as 100 mL and, more typically, 500 mL of intraperitoneal fluid that ranges from 60 to 95% in most recent studies, and specificity for hemoperitoneum is excellent.[62] Therefore when time is precious in the patient in critical condition, the FAST can provide a rapid answer to the key question in the decision matrix, which is whether hemoperitoneum is present. Unlike DPL, the FAST can evaluate intrathoracic structures, is noninvasive, and can be performed serially and by multiple technicians. Unlike CT scanning,

www.ketabpezeshki.com 66485457-66963820

it is not a potential radiation hazard and does not require administration of contrast agents. Accuracy correlates with length of training and experience, but expertise can be readily achieved in emergency medicine and surgical training programs.[63] Serially performed FAST increases its diagnostic accuracy for organ injury in patients with BAT.[64,65] Furthermore, E-FAST adds thoracic windows to detect the presence of pneumothorax in patients who have sustained penetrating abdominal trauma (PAT) or BAT. These additional views detect pneumothorax with a sensitivity of almost 60% and a specificity of up to 99% when compared with CT, but more important, the E-FAST is three times as sensitive as a portable supine chest x-ray examination done in the trauma bay, which has a sensitivity of only 20%.[66] Overall, ultrasonography can serve as an accurate, rapid, and less expensive diagnostic screening tool than DPL or CT.[67-69]

Disadvantages. The FAST study does not image solid parenchymal damage, the retroperitoneum, or diaphragmatic defects well. It is technically compromised by the uncooperative, agitated patient, as well as by obesity, substantial bowel gas, and subcutaneous air. Indeterminate studies require follow-up attempts or alternative diagnostic tests.[65] It is less sensitive and more operator dependent than DPL in revealing hemoperitoneum and cannot distinguish blood from ascites or uroperitoneum. For unclear reasons, ultrasound has a high (31%) false-negative rate in detecting hemoperitoneum in the presence of pelvic fracture.[70] The FAST study, like DPL, will not detect the presence of solid parenchymal damage if free intraperitoneal blood is absent, as in subcapsular splenic injury.[70,71] Finally, ultrasonography is poor at recognizing bowel injury in which hemorrhage tends to be inconsequential, and failure to diagnose hollow viscus perforation in a timely manner can have catastrophic results.[72] Because of these limitations, reliance on a single negative FAST examination performed within minutes of the injury is ill-advised. Serial FAST examinations may help to determine progressive hemorrhage, however.

Diagnostic Peritoneal Lavage

Although largely supplanted by the FAST examination and CT scanning, DPL (and more commonly aspiration) still has a role in certain cases. DPL comprises two interrelated steps. The first is the attempted aspiration of free peritoneal blood. The recovery of 10 or more mL of frank blood from the peritoneum is a strong predictor of intraperitoneal injury, and the procedure is then terminated. If aspiration findings are negative, lavage is conducted in which the peritoneal cavity is washed with saline. This fluid is introduced by catheter, recovered by gravity drainage, and analyzed. The sole absolute contraindication to DPL is the established need for laparotomy. Relative contraindications include prior abdominal surgery or infections, coagulopathy, obesity, and second- or third-trimester pregnancy.

Advantages. In cases of blunt trauma, DPL's primary remaining use is in the triage of the patient who is hemodynamically unstable and has multiple injuries with an equivocal FAST examination or in the patient in whom FAST cannot be obtained owing to the absence of equipment or competent personnel.[73] In such complex scenarios, DPL can promptly reveal or exclude the presence of intraperitoneal hemorrhage and can serve as an indication for laparotomy. Rarely, DPL is used to discern potentially serious bowel perforations in patients who are poor candidates for serial clinical observations (e.g., coma) and for which other diagnostic methods can be unreliable.[74]

Disadvantages. The morbidity associated with DPL occurs at a low rate and can be categorized as local or systemic infection, intraperitoneal injury, and technical failure. Wound complications, including hematoma and infection, occurred in 0.3% of cases in two large reviews.[75] Technical failure can result in an inaccurate study and difficulty with fluid collection. In addition, DPL is exquisitely sensitive for hemoperitoneum and in a hemodynamically stable patient can lead to unnecessary laparotomy. False-negative interpretations can result from the failure to recover lavage fluid.

Table 46-2 Diagnostic Peritoneal Lavage Red Blood Cell Criteria (per mm^3)

	POSITIVE	INDETERMINATE
Blunt trauma	100,000*	20,000-100,000
Stab wound		
Anterior abdomen	100,000	20,000-100,000
Flank	100,000	20,000-100,000
Back	100,000	20,000-100,000
Low chest	5000-10,000	1000-5000
Gunshot wound	5000-10,000	1000-5000

*In a hemodynamically stable patient with pelvic fracture and positive or equivocal red blood cell count, computed tomography should be obtained to corroborate or refute intraperitoneal injury.

Results. In cases of blunt trauma, the aspiration of 10 mL or more of blood has a positive predictive value of greater than 90% for intraperitoneal injury, predictably solid visceral or vascular, and is responsible for approximately 80% of true positive DPL findings in blunt trauma.[75] The red blood cell (RBC) count of the lavage fluid is the next most widely used and accurate parameter (Table 46-2). In cases of blunt trauma, an RBC count exceeding 100,000/mm^3 is considered positive and generally specific for injury. However, while sensitive to the presence of injury, it may detect self-limited pathology for which laparotomy is unnecessary.

There is a well-known association between false-positive peritoneal lavage in the setting of retroperitoneal hematoma and pelvic fracture.[76] CT scanning is the standard method by which pelvic fracture with possible retroperitoneal or intraperitoneal hemorrhage is evaluated.[77]

With anterior abdominal stab wounds, aspiration of 10 mL of gross blood or the return of lavage fluid with an RBC count greater than 100,000/mm^3 carries a sensitivity exceeding 90% (see Table 46-2).[78] It is recommended that patients with equivocal RBC counts be carefully observed for 12 to 24 hours.[79] Most injuries associated with RBC counts less than 100,000/mm^3 are to hollow viscera, and clinical manifestations of these should develop within this observation period. With lower chest stab wounds, a positive RBC count of 5000 to 10,000/mm^3 should be considered to be evidence of diaphragmatic injury. Because of the more serious nature and greater likelihood of an injury with abdominal GSWs, RBC counts of 5000/mm^3 are advocated as the cutoff, as these will signal peritoneal penetration, if not injury.[75] However, laparoscopy has supplanted DPL for the purpose of identifying or excluding diaphragmatic injury in lower chest penetrating trauma.

Local Wound Exploration

Because stab wounds do not reach the peritoneum in a significant number of cases, LWE is useful in determining the depth of penetration. The wound should be infiltrated with a local anesthetic containing epinephrine and thoroughly prepared for exploration. The stab wound may be extended if required and then carefully visualized through each successive layer of tissue. Blind probing with digits, instruments, or cotton-tipped swabs is inaccurate, unless the peritoneal cavity is obviously freely entered. Blind probing of chest injuries adds no potential additional information and may be hazardous. If LWE indicates that the peritoneum is violated, further diagnostics are indicated. Likewise, when the end of the wound tract cannot be determined clearly, peritoneal entry

www.ketabpezeshki.com 66485457-66963820

is presumed. When the stab wound is documented to be superficial to the abdominal cavity, the patient can be safely discharged home after appropriate wound care.[80]

LWE is generally advocated in cases of anterior abdominal stab wounds, but in other areas the decision is less clear. Abdominal, flank, and back wounds have been evaluated with this method, particularly when the entry is more superficial.[13,14,81] The flesh of obese or heavily muscled patients in particular can present technical problems and decrease the reliability of exploration while increasing its risk. Wound explorations in patients with multiple entrances are not economical and require extensive effort, and it may be wiser to assume peritoneal penetration. Deep exploration over the thoracic cage is precluded by attendant complications to neurovascular structures and pleura. However, careful inspection of superficial chest wounds (e.g., slash wound) is safe and can provide valuable data. CT, laparoscopy, or thoracoscopy is occasionally used in lieu of LWE.

Special Procedures

Laparoscopy

Laparoscopy is increasingly finding a role in some trauma centers. General anesthesia in an operating suite is required. Laparoscopy has been most useful in assessing penetrating trauma, especially for injury to the diaphragm and intrathoracic abdominal organs.[82] It has a reported sensitivity of 87.5% and specificity of 100% for detection of diaphragmatic injury after PAT, with a positive predictive value of 100% and negative predictive value of almost 97%.[83] Organs repaired via the laparoscope include the diaphragm, solid intraperitoneal viscera, stomach, and small bowel. Wound tracts have been assessed as accurately as by LWE. Very little experience in blunt trauma has been documented thus far.

Drawbacks of laparoscopy include poor sensitivity for hollow visceral injury, notably to the small bowel, and difficulty in assessing the retroperitoneum and extent of damage to the liver and spleen.[83] Complications can result from trocar misplacement. If the diaphragm has been violated by the original trauma, pneumothorax or tension pneumothorax can occur during the insufflation phase. At this time the greatest value of laparoscopy is in the evaluation and management of equivocal penetrating wounds to the thoracoabdominal region of stable patients. This approach can realize a reduced incidence of nontherapeutic laparotomy.[84,85]

DIFFERENTIAL CONSIDERATIONS

Trauma versus Medical Condition

Medical and traumatic pathologic conditions can be coincident or lead one to the other. For instance, hypoglycemia or a generalized convulsive seizure may precipitate an MVC, and the patient's altered mental status may incorrectly be ascribed to closed head injury, delaying diagnosis of the medical condition. Patients with infectious mononucleosis can experience splenic rupture after relatively trivial trauma, and presentation may be delayed. Finally, patients with premorbid coagulopathy or who are on therapeutic anticoagulation may sustain serious intracranial hemorrhage from otherwise unconcerning head trauma.

Single versus Multisystem Trauma

Emergency physicians should be wary and not miss the proverbial forest for the trees. For instance, the pedestrian struck by a car who has an alleged isolated tibial-fibular fracture may well harbor significant intra-abdominal pathology, irrespective of a nontender abdomen.

Single versus Multiple Intraperitoneal Organ Injury

There has been an increasing trend toward nonoperative management of known intraperitoneal solid organ injury, specifically of the spleen and liver. It must be remembered, however, that coincident hollow viscus pathologic lesions may exist but not be discernible initially on clinical examination or certain diagnostic studies. In addition, patients without solid organ pathology who have increased amounts of free peritoneal fluid warrant careful consideration for hollow viscus damage.

Intraperitoneal Injury versus Necessary Laparotomy

Formerly, suspicion or knowledge of any intraperitoneal injury mandated laparotomy. Now, diagnostic effort is appropriately aimed at determining whether surgery is necessary or whether the injury is self-limited and does not require repair measures.

MANAGEMENT

General Measures

Prehospital

The field approach to multiple or serious trauma focuses on rapid transportation to a capable receiving emergency department. The initial measures taken vary with the need for active airway management, the presence of concomitant injuries, and the skills of the prehospital personnel. Hemorrhage is the major life threat in cases of PAT or BAT, and two large-bore intravenous lines should be inserted in transit when possible,[86] though delay at the scene for insertion of intravenous lines should not occur unless extrication is prolonged. Penetrating wounds and eviscerations in particular should be covered with sterile dressings. Contact should be made with the base-station physician to communicate pertinent matters of the history, vital signs, treatment measures and their effects, and estimated time of arrival. Certain authors advocate for direct transport to high-level trauma centers unless airway management is a concern.[87]

Emergency Department

The general principles of trauma care apply (see Chapter 36). The use of diagnostic aids for abdominal trauma should be carefully restricted according to the patient's stability and the usefulness of the information sought in guiding management. Patients who do not require immediate laparotomy will likely undergo one or more diagnostic procedures to determine whether abdominal injury exists and, if so, whether operative intervention is necessary.

Thoracotomy. Thoracotomy and subsequent cross-clamping of the descending aorta have been used to stabilize patients with thoracoabdominal injuries and profound hypovolemic shock. However, it is rarely lifesaving in the emergency department (see Chapter 45).

In a patient with massive abdominal injuries and hypotension secondary to a hemoperitoneum, the primary purpose of aortic cross-clamping is to shunt available blood into the coronary and cerebral circulation during resuscitation. Second, it is helpful in providing proximal bleeding control of certain vascular and parenchymal injuries, although continued bleeding can occur via collateral flow, until direct clamping, packing, or repair is achieved. Third, it can allow direct atrial access for rapid fluid administration. Finally, it has been advocated as a prophylactic measure in the operating room before laparotomy is performed for a massive hemoperitoneum. In certain instances, abdominal decompression,

www.ketabpezeshki.com 66485457-66963820

particularly in the face of a vascular injury, may result in worsening shock and death.

Antibiotics. An intestinal perforation and spillage can occur after blunt or, more commonly, penetrating trauma to the abdomen. Anaerobes and coliforms are the predominant organisms found. Antibiotics given prophylactically have been demonstrated to be effective in decreasing the incidence of intra-abdominal sepsis and should be given as soon as such an injury is suspected. A single preoperative dose of a broad-spectrum antibiotic or combination of antibiotics that covers both aerobic and anaerobic organisms, such as piperacillin-tazobactam 3.375 g intravenously, is recommended.[88]

Penetrating Abdominal Trauma: Stab Wounds

Diagnostic Studies

The purpose of diagnostic studies is to determine whether the peritoneal cavity has been violated or whether there is intraperitoneal injury requiring operative repair. Tests used for the former purpose include plain films, LWE, ultrasonography, and laparoscopy. Those most commonly used with the latter intent are serial physical examinations, CT scans, FAST, DPL, and laparoscopy. These modalities are undertaken only if clinical determinants that would indicate the need for emergent laparotomy are not present.

Management

Selective management of abdominal stab wounds is now well accepted because of the relatively low incidence of intraperitoneal injuries coupled with the success of various diagnostic strategies.[89,90] The appropriateness of these strategies is predicated on the site of penetration, the clinical status of the patient, and the experience and preference of an institution and its personnel. Formerly, the goal of mandatory exploration of all stab wounds was to eliminate missed injuries. Currently, selective management has resulted in a tremendous reduction in unnecessary laparotomies and their associated morbidity, with minimal and acceptable loss in sensitivity for significant intraperitoneal injury.[90] Although certain authors promote the relative safety of nontherapeutic operations, others cite considerable immediate and delayed hazards, as well as increased cost.[80] It is generally preferred that the nondiagnostic laparotomy rate be less than 15%.

Anterior Abdomen. In approaching the management of stab wounds to the anterior abdomen, the clinician is faced with three fundamental tasks. The first and most important is to determine whether clinical indications exist for laparotomy. The presence of one or more of these indications, particularly in the context of an unstable patient, sets the course to exigent operation. If none is found, however, the clinician may address the second issue of whether the peritoneal cavity has been violated. If it can be definitively demonstrated that it has not, no further diagnostic evaluation is required, and the patient can be discharged after appropriate wound care. If the cavity has been violated, or if it cannot be determined that the cavity has not been violated, the third question is pursued: does injury exist and, if so, is laparotomy required? One general approach to abdominal stab wounds founded on these three queries is summarized in Figure 46-9. This algorithm is largely based on clinical indicators of injury, LWE, CT, and other radiologic modalities. In centers without such resources, diagnostic peritoneal aspiration and lavage may still have a limited role. Other strategies rely more heavily on other techniques, such as serial abdominal examinations or laparoscopy.[91-94]

Step I: Clinical Indications for Laparotomy. Seven clinical determinants are used to predict the need for laparotomy after stab wounds to the abdomen (Table 46-3). Although there is

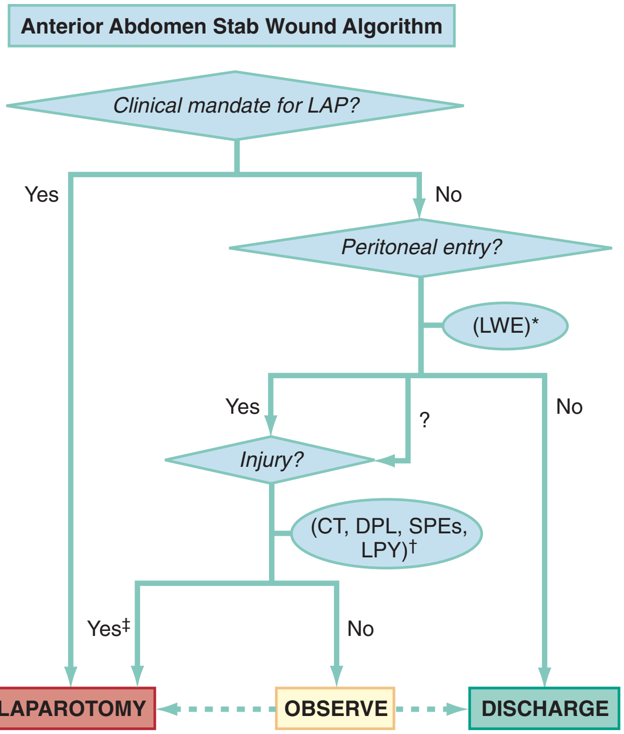

Figure 46-9. Anterior abdomen stab wound algorithm. *LAP,* laparotomy; *LWE,* local wound exploration.
*Plain films, focused assessment with sonography in trauma (FAST), laparoscopy (LPY), and computed tomography (CT) can also assess peritoneal entry.
†CT, diagnostic peritoneal lavage (DPL), serial physical examinations (SPEs), or LPY can be used in singular or complementary fashion, depending on the clinical scenario.
‡Expectant management of injuries is infrequently attempted.

Table 46-3 Clinical Indications for Laparotomy Following Penetrating Trauma

MANIFESTATION	PREMISE	PITFALL
Hemodynamic instability	Major solid visceral or vascular injury	Thorax or mediastinum, causal or contributory
Peritoneal signs	Intraperitoneal injury	Unreliable, especially immediately postinjury
Evisceration	Additional bowel, other injury	No injury in one fourth to one third of stab wound cases
Diaphragmatic injury	Diaphragm	Rare clinical, radiographic findings
Gastrointestinal hemorrhage	Proximal gut	Uncommon, unknown accuracy
Implement in situ	Vascular impalement	Comorbid disease or pregnancy creates high operative risk
Intraperitoneal air	Hollow viscus perforation	Insensitive; may be caused by intraperitoneal entry only or may have cardiopulmonary source

Modified from Marx JA: Diagnostic peritoneal lavage. In Ivatury RR, Cayten CG (eds): The Textbook of Penetrating Trauma. Baltimore, Williams & Wilkins, 1996.

www.ketabpezeshki.com 66485457-66963820

general consensus regarding the reliability of some of these, each has suboptimal predictive value.

1. *Hemodynamic compromise.* This is the preeminent indication of the need for laparotomy and is the most likely reason that a patient will be taken urgently to the operating room without preliminary diagnostic studies. This is typically an appropriate approach after middle and lower abdominal penetration.[94-96] However, stab wounds to the upper abdomen and lower chest may produce hemodynamic instability because of intrathoracic hemorrhage, pneumothorax, or pericardial tamponade.
2. *Peritoneal signs.* There is considerable debate over the reliability of peritoneal signs, particularly in the early postinjury period. Among physical examination findings, unequivocal peritoneal signs have the highest positive predictive value, whereas an entirely normal examination even in the presence of mild to moderate intoxication has the greatest negative predictive value for therapeutic laparotomy.[95,96]
3. *Evisceration.* With isolated omental evisceration, both a selective and a mandatory operating approach have been espoused. Omentum has been successfully ligated, excised, and restored to the peritoneal cavity.[94,95] However, patients with viscus or omental evisceration sustain up to an 80% incidence of major intraperitoneal injury, rendering laparotomy a reasonable next step in management.[12]
4. *Left-sided diaphragmatic injury.* In contradistinction to blunt mechanisms, penetrating trauma to the diaphragm produces small tears and evanescent clinical clues to their presence. Thus clinical examination and plain chest films are rarely diagnostic of injury. Left-sided tears in the diaphragm can lead to herniation of bowel into the thorax weeks to decades later, leading to obstruction, strangulation, infarction, perforation, and death. For right-sided diaphragmatic injury, the liver affords considerable protection against herniation. Other diagnostic measures, such as DPL or laparoscopy, or a mandatory laparotomy approach are necessary to determine whether the diaphragm has been violated.[97]
5. *Gastrointestinal hemorrhage.* Recovery of blood via a nasogastric tube or emesis may reflect a violation of the stomach or duodenum but is an unusual occurrence.[80,94,96] Likewise, examination of the rectum or vagina may reveal hemorrhage that is the result of intraperitoneal or retroperitoneal trauma, but there are often external signs of hemorrhage. Care should be taken in performing a vaginal examination in a woman with pelvic fractures to avoid injury to the examiner's hand.
6. *Implements in situ.* The conservative and widely held maxim is to remove implements in situ of the torso in the operating room. This is to ensure expeditious control of hemorrhage should the implement reside within a vascular space or highly vascularized organ. Although implements in situ are most safely removed in the operating room, exceptions to this practice exist. These include situations in which emergency department resuscitation is impeded by the presence of the implement or the patient is at high risk of significant morbidity from nontherapeutic laparotomy because of severe comorbid conditions or pregnancy, for example.
7. *Intraperitoneal air.* The presence of free intraperitoneal air is often not sought because of the insensitivity and nonspecificity of this finding. Free intraperitoneal air can impute communication of the knife with the intraperitoneal space or the presence of pulmonary or mediastinal injury. Therefore it does not necessarily indicate hollow visceral perforation and should not be used in isolation as an indicator for operation.

Step II: Peritoneal Violation. If clinical indications for laparotomy are absent, a logical next step is assessing the wound tract itself. The presence of peritoneal violation can be determined by a variety of means. There is great value in establishing that a wound tract is superficial to the peritoneal, retroperitoneal, intrathoracic, and pericardial cavities. In this event, the patient can be discharged from the emergency department after receiving appropriate wound care.[91,95] If a study is inconclusive, it should be assumed that one or more of these cavities has been violated and further means of assessment are required. The five methods of assessing the intactness of the peritoneum are as follows:

1. *Evisceration.* Evisceration of bowel or omentum is clear evidence of peritoneal entry. These situations are usually handled by mandatory laparotomy. In certain centers, however, these eviscerations are reduced in the emergency department and further diagnostics pursued.[61,96]
2. *Intraperitoneal air.* A finding of intraperitoneal free air on an upright chest or a lateral decubitus abdominal radiograph generally establishes that the knife has entered the peritoneal cavity and drawn air in with it, has disrupted a hollow viscus, or both. Rarely, a false-positive determination of peritoneal entry can be made when the actual source of intraperitoneal free air is the pulmonary tract.
3. *LWE.* This has been demonstrated to be an effective tool in determining the depth of the stab wound tract.
4. *Ultrasonography.* Ultrasonography demonstrating hemoperitoneum, pneumoperitoneum, or pericardial effusion identifies peritoneal penetration or cardiac injury.[98] However, its reliability as a sole indicator for injury is not as dependable as that in BAT, and it carries a 15% negative laparotomy rate when used as such. In addition, a negative FAST does not rule out peritoneal violation.[99] Ultrasonography may also be used as an adjuvant to LWE to determine intactness of fascia. Although a small study demonstrated that it can positively rule in fascial penetration, it is unreliable to rule this out.[81] Experience with ultrasonography for this purpose has been successful but very limited.
5. *Laparoscopy.* This has compared favorably with LWE in assessing the wound tract but requires far more expertise and carries a far greater risk of complications. It is the most invasive and costly means of evaluating the integrity of the peritoneum. However, laparoscopy may also discover and serve as the mode of repair of certain diaphragmatic or organ injuries or both,[12,83,84] and some postulate that its use in experienced centers actually decreases length of stay and therefore cost.[94]

Step III: Injury Requiring Laparotomy. In this algorithm, patients requiring an operation on clinical grounds have proceeded to laparotomy, and those in whom peritoneal, retroperitoneal, intrathoracic, and pericardial cavity violations have been excluded are discharged home. The patients remaining have presumed or known peritoneal violation. The next consideration is whether injury exists that dictates operative repair, because organ injury is present in only just over 60% of patients with peritoneal violation.[4,92] In any case, patients who reach this stage of evaluation should be observed for at least 12 to 24 hours.[75]

Historically, the diagnostic standard to address the issue of intraperitoneal injury was DPL. Its role was especially valuable as a rapid means of determining hemoperitoneum in the patient in critical condition and for the discovery of occult hollow viscus perforation and isolated diaphragmatic injury.[97,100] However, it is invasive, and thus the vast majority of centers advocate other, less

www.ketabpezeshki.com 66485457-66963820

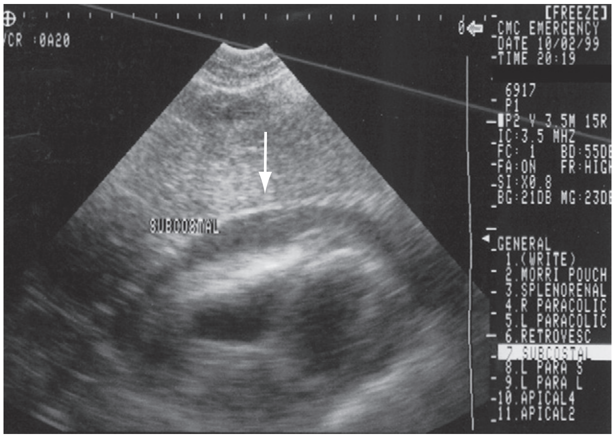

Figure 46-10. Pericardial effusion seen on subcostal view *(arrow).* The white line is the pericardium, and the anechoic space below represents a fluid collection in the pericardial space.

invasive adjuvant testing coupled with serial physical examinations as the next step in management.

Ultrasonography may be somewhat less accurate than DPL in establishing the presence or absence of hemoperitoneum, but it can simultaneously ascertain hemopericardium (Fig. 46-10). In most centers ultrasonography can be accomplished as quickly or more quickly than peritoneal aspiration. Emphasis on serial examinations with selective use of other studies on an as-needed basis can be successful when an adequate number of experienced clinicians are available.[98,101,102]

CT has been particularly useful for potential colorectal trauma or further assessment of patients submitted to serial examination alone. However, some centers routinely perform CT in these cases and not simply for possible colorectal trauma.[103] Most use triple contrast (oral, rectal, and intravenous), although some newer studies cite equal accuracy with intravenous contrast only.[104] Hollow viscus and occult diaphragmatic injuries remain the most frequently missed injuries on CT (even with use of triple contrast), although with the advent of multidetector CT scanners this is decreasing.[11,83]

Laparoscopy works best in experienced hands for restricted indications. However, its routine use is gaining favor in some institutions. Benefits include the ability to detect organ injury (including diaphragmatic injury) and simultaneously repair some injuries, thus decreasing negative and nontherapeutic laparotomy rates.[11,81,84]

Thoracoabdominal. Even a single stab wound to the low chest can violate the mediastinum, thoracic cavity, diaphragm, peritoneal cavity, and retroperitoneum. The risk of diaphragmatic penetration from a left thoracoabdominal stab wound has been measured at 17%.[12] When all thoracoabdominal wounds are considered, the risk of occult injury is 7%.[105] Ultrasonography can be extremely useful by permitting quick assessment for hemopericardium and hemoperitoneum in the marginally stable patient, if thoracotomy or laparotomy is not already clinically indicated.[75] LWE of slash-type wounds may obviate the need for further evaluation. However, the depth of investigation cannot be taken beyond the anterior rib margin to maximize safety and accuracy. Further assessment for intraperitoneal and diaphragmatic injury can be made by DPL. The RBC criterion is lowered to 5000 to 10,000/mm^3 to optimize sensitivity for isolated diaphragmatic injury.[104] Laparoscopy or thoracoscopy can visualize and potentially be used to repair the diaphragm and other organs. Newer multidetector CT scanning and MRI show promise in excluding diaphragmatic injury. CT has a sensitivity of 94% and specificity of almost 96% for detecting diaphragmatic injury. However, equivocal scans should be followed up with more definitive management, such as DPL, exploratory laparotomy, or laparoscopy.[13] A very conservative approach to the left lower chest stab wound, in particular, is mandatory exploration. This approach avoids any opportunity for missed diaphragmatic rents and their delayed consequences but results in an exceptionally high incidence of nontherapeutic operation. Rapid slice helical CT and MRI may provide a solution to this vexing concern, but data are limited to date.

Flank and Back. The incidence of retroperitoneal injuries after stab wounds to the flank and back is greater than with injury to the anterior wall. However, risk of intraperitoneal organ injury is significant, ranging from 15 to 40%.[14] Again, LWE can be a useful first step. However, the paraspinal muscles are quite thick, rendering the procedure more difficult. Triple-contrast CT scan is becoming the preferred method of evaluation in hemodynamically stable patients and coupled with observation may safely allow nonoperative management of these patients.[32,97]

Implement in Situ. It is routinely advised that foreign bodies in situ of the torso be removed under operating conditions. This is considered safest in the event that the implement is intravascular or in a highly vascularized organ. Plain films are generally all that is required. A CT scan may be indicated in stable patients if plain films suggest impalement of major vascular structures. Angiography may also be necessary. For pregnant patients or those with severe comorbid illness in whom unnecessary laparotomy is preferably avoided, a CT scan may be able to discern the depth of entry and extent of injury, though the risk of radiation to the fetus must be weighed against the risk of operative intervention. In these cases the foreign body may be removed safely outside of the operating room.

Penetrating Abdominal Trauma: Gunshot Wounds

Diagnostic Studies

Diagnostic studies are used in a fashion similar to that for stab wounds. Moreover, the same diagnostic agents are applied, although in more restricted circumstances. The principal uses of diagnostic studies are to determine whether the missile has entered the peritoneal cavity and whether injury requiring operative intervention has occurred.

Management

Like stab wounds, GSWs typically produce multiple organ injuries and a high incidence of hollow visceral injury. However, the risk of mortality is significantly greater, especially if vascular structures are involved. Missiles striking the low chest commonly penetrate both intrathoracic and abdominal structures, including the diaphragm.

Abdominal GSWs enter the peritoneal cavity in approximately 80% of cases, and in more than 90% of those involving penetration, there is intraperitoneal damage.[30] These statistics significantly exceed the figures for stab wounds, and most trauma surgeons adjust their management to a conservative bent accordingly. We promote the principle that although selective management is widely accepted for stab wounds, its application in the management of GSWs is more limited, and therefore conservative clinical criteria for mandatory laparotomy should be applied. Other authors argue, however, that although peritoneal penetration and intraperitoneal injury are far more likely to result from GSWs, damage requiring operative repair should be the instrumental concern, and this may be less common than previously stated. More recent series report intra-abdominal injury in only 70 to 80% of cases, supporting the contention that nonoperative management could be appropriate for a substantial percentage of patients.[3,30,103]

www.ketabpezeshki.com 66485457-66963820

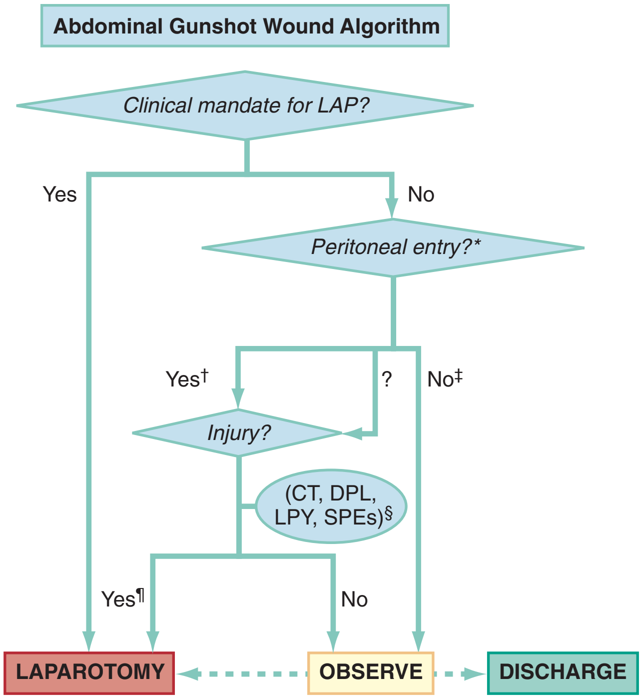

Figure 46-11. Abdominal gunshot wound algorithm. *LAP,* laparotomy. *Can be assessed by missile path, plain films, local wound exploration, ultrasonography, and laparoscopy.
†Most centers proceed to laparotomy if peritoneal entry is suspected.
‡Patients with documented superficial and low-velocity injuries can be discharged; unknown-depth or high-velocity injuries require further tests or observation.
§Computed tomography (CT), diagnostic peritoneal lavage (DPL), laparoscopy (LPY), or serial physical examinations (SPEs) can be used in singular or complementary fashion, depending on the clinical scenario.
¶Expectant management of injuries caused by gunshot wounds is rarely attempted.

A prudent approach to GSWs to the abdomen can follow the same sequential three-step algorithm as for stab wounds (Fig. 46-11). First and foremost, are there clinical grounds for operation? Second, if none exists, has peritoneal violation occurred? Third, does injury requiring laparotomy exist? Centers that adhere to the tenet that known or suspected peritoneal violation imputes high likelihood of intraperitoneal injury will proceed to laparotomy if the second question is answered affirmatively. Those in which it is believed that there is a lower incidence of significant organ damage use other diagnostic agents, including serial physical examination, irrespective of whether the peritoneal cavity has been violated.

Step I: Clinical Indications for Laparotomy. These clinical demands are similar to those proposed for stab wounds (see Table 46-3).

Step II: Peritoneal Violation. Six methods are used to determine whether the missile has entered or traversed the peritoneal cavity. This question is most germane for centers that perform laparotomy based on peritoneal violation alone.

1. *Missile path.* Clear entrance and exit wounds allow for a reasonably reliable estimate of the missile path. However, many GSWs ricochet. Even a single GSW can ricochet, and the tendency of low-velocity missiles to follow fascial planes of lower resistance can render this approach misleading.
2. *Plain radiographs.* An anteroposterior and lateral projection of the abdomen can assist in placing the missile in the peritoneal cavity, but such estimations are imprecise and are largely unhelpful in patients with through-and-through or multiple GSWs.
3. *LWE.* Because GSWs produce considerably more tissue damage than stab wounds, LWE is a less useful tool for GSWs of the abdomen, flank, and back. Its role should likely be restricted to low-velocity projectiles with suspected superficial entry. Because of the much greater technical difficulty and hazard in visualizing these extensive missile tracts, there is a tendency to underestimate the degree of damage.[30]
4. *Ultrasonography.* The experience with ultrasonography in coincidentally assessing wound tracts and the mediastinum for low chest and upper abdominal penetration has been successful but very limited.
5. *Laparoscopy.* Laparoscopy is the most invasive and costly means of evaluating the integrity of the peritoneum. However, it may also discover and serve as the mode for repair of certain diaphragmatic or organ injuries or both.[82,84,102]
6. *CT.* CT has been helpful when trajectory is indeterminate and has shown a sensitivity and specificity of 90.5% and 96%, respectively, for identifying intra-abdominal injury. It can also identify the wound track and indicate vascular structures at risk for injury, although this is more useful in neck wounds.[30,103]

Step III: Injury Requiring Laparotomy. In most institutions, the algorithm terminates after the second step, in which determination or strong suspicion of peritoneal violation presupposes the need for laparotomy. At more liberal centers, these facts are deemed insufficient, and additional diagnostics are undertaken.

1. *Serial examinations.* Patients with normal examination findings or localized wound tenderness can be observed only if clinical circumstances and institutional policy allow. Physical examination may be more reliable than previously suspected in the presence of alcohol or illicit drug intoxication.[75]
2. *DPL.* DPL has been highly successful in determining or excluding intraperitoneal injury. When DPL is used, all criteria for positivity remain the same with the exception of the RBC count, which is lowered to 5000 to 10,000 RBCs/mm^3 to maximize sensitivity.[30,103]
3. *CT.* Higher-resolution scanners may augment the ability of CT to identify hollow visceral damage in addition to solid organ and vascular pathologic lesions.[30]
4. *Laparoscopy.* The greatest use for laparoscopy is in the evaluation of the diaphragm in patients with left thoracoabdominal GSWs who do not have indications for standard operative intervention.[89]

Thoracoabdominal. Patients with GSWs to the low chest have intraperitoneal injuries reported in 45% of cases. Clinical indications for laparotomy are unchanged. DPL is particularly helpful in these cases to discern diaphragm injury, and the RBC threshold of 5000 to 10,000/mm^3 produces excellent sensitivity, but a combination of CT scanning and serial examinations is more commonly used.

Flank and Back. In the past, operative exploration was generally recommended because of the increased likelihood of a serious injury and the greater fallibility of both the physical examination and DPL in cases of retroperitoneal injuries. However, as multidetector CT scanners have evolved, an intravenous contrast CT scan to delineate retroperitoneal pathologic lesions is typically the initial diagnostic test of choice in a stable patient.[95,102] As with stab wounds, laparoscopy or observation alone can be attempted in selected circumstances.[106]

Shotgun Wounds. Type I injuries can be effectively managed by reserving laparotomy for patients with clear peritoneal signs or progressive abdominal tenderness. Certain authors advocate an expectant approach to type II injuries, stating that small punctures of the bowel cause no wound eversion and no peritoneal

www.ketabpezeshki.com 66485457-66963820

leakage and will spontaneously close.[107] A more prudent approach is to perform laparotomy in cases of these penetrating wounds, especially if there are signs of peritonitis. Reconstruction of abdominal wall defects may be required. Type III injuries are commonly associated with multiple organ injuries, shock, and pronounced tissue destruction, requiring hemostasis and extensive débridement.

Blunt Abdominal Trauma

Diagnostic Studies

Most centers assimilate physical examination, bedside ultrasonography, CT, and, in rare instances, DPL into a clinical algorithm.[25] Other tests, such as angiography, may be indicated. To reiterate, a clinical assessment of an alert patient that depends on abdominal findings alone is reasonably accurate but is accompanied by both false-positive and false-negative errors.[67,108-110] Such an assessment is more hazardous for a patient who is under the influence of a variety of toxins or whose examination is compromised by a head injury, spinal injury, or difficulty in communication resulting from developmental delay, psychiatric illness, a language barrier, or age.

The purpose of diagnostic studies in patients with BAT is twofold (Table 46-4): to discern or eliminate the presence of hemoperitoneum in the patient whose condition is critical and unstable to properly sequence management and, in less urgent circumstances, to demonstrate organ injury that requires operative repair.

Determining Hemoperitoneum

FAST Ultrasonography. The FAST examination has a safety advantage in that it can be performed rapidly and conducted in the resuscitation suite in the emergency department. In contradistinction to DPL, the FAST is hazard-free, and serial examinations can be undertaken with ease in any patient. In hypotensive patients the FAST has excellent sensitivity for hemoperitoneum requiring surgical intervention, and most centers proceed to exploratory laparotomy in these patients.[107,111] However, in those with a negative FAST, intra-abdominal injury requiring operative repair cannot be excluded.[112,113]

Diagnostic Peritoneal Lavage. DPL is exceptionally sensitive in discovering hemoperitoneum, with a false-negative rate of less than 2%. This procedure can be performed in virtually any patient by varying the site and technical method. Aspiration of the peritoneum generally requires less than 5 minutes. Given advances in other diagnostic modalities, however, its role is now predominantly at centers without access to ultrasound in hemodynamically unstable patients.

Computed Tomography. Although a CT scan can both visualize and estimate the quantity of hemoperitoneum, the time required to accomplish the procedure, including transport of the patient and setup, can be problematic, depending in part on the location of the scanner. Moreover, the ability to carry out CT scanning in a safe manner depends on the availability and expertise of personnel to monitor the patient while he or she is in the CT scanner.

Demonstrating Organ Injury That Requires Laparotomy.

Indications for the respective studies will vary with clinical need and with the experience, resources, and attitudes of individual institutions.

Ultrasonography and Diagnostic Peritoneal Lavage. Prompt FAST (or, less commonly, DPL) is clearly warranted in the acutely injured and unstable patient with multiple trauma.

The primary value of the FAST is in the search for hemoperitoneum. It is far less reliable in specifying organ pathology, with the exception of traumatic pancreatic pseudocysts.

Computed Tomography. A CT scan alone is sufficient and appropriate in the patient who is hemodynamically stable and has no obfuscating clinical factors. The great advantage of the CT scan is its ability to distinguish intraperitoneal organ injury and simultaneously evaluate the retroperitoneum. It is the most capable instrument in diagnosing liver and spleen pathologic lesions, and it allows visualization and semiquantitation of hemoperitoneum.

Laparoscopy. At this time, the role of laparoscopy in trauma cases is relegated mostly to injuries with a penetrating mechanism.

Table 46-4 Diagnostic Studies in Blunt Abdominal Trauma

STUDY SCENARIO	PRIMARY PURPOSE	STUDY	COMPENSATORY
Hemodynamically Unstable			
General	IPH	FAST, DPA	—
Pelvic fracture	IPH	FAST, DPA*	—
Hemodynamically Stable			
General	OI[†,‡]	FAST, CT	DPL, SPEs
Nonoperative management[§]	OI	FAST, CT[‖]	DPL,[¶] SPEs
CHI	OI, HVI	FAST, CT[‖]	SPEs[#]
BAI	IPH	FAST, DPA	CT**

BAI, blunt aortic injury; *CHI,* closed head injury; *CT,* computed tomography; *DPA,* diagnostic peritoneal aspiration; *DPL,* diagnostic peritoneal lavage; *FAST,* focused assessment with sonography in trauma; *HVI,* hollow viscus injury; *IPH,* intraperitoneal hemorrhage; *OI,* organ injury; *SPEs,* serial physical examinations.
*Positive peritoneal aspirate necessitates laparotomy, positive red blood cell count only, and warrants attention to pelvic fracture.
†To discover fluid or blood suggesting injury.
‡FAST for OI much less reliable than for IPH.
§Institutional capability should be carefully considered.
‖CT less reliable for HVI than for solid visceral injury.
¶Complementary to CT if HVI suspected.
#SPEs are unreliable in the patient with CHI.
**May be more appropriate if helical CT is primary study for blunt abdominal injury or can be rapidly acquired.

Management

In cases of blunt trauma, it is the exception when a patient undergoes laparotomy based on clinical grounds alone. Far more typically, one or a complementary battery of diagnostic tests are performed. The choice of these tests is influenced by the patient's hemodynamic status, the clinical scenario, and the institution's resources and preferences (Fig. 46-12).

Clinical Indications for Laparotomy. The decision to perform immediate laparotomy after injury from a blunt mechanism is rarely determined solely by clinical parameters. Potential indications are any of the following (Table 46-5):

1. Unexplained signs of blood loss or hypotension in a patient who cannot be stabilized and in whom intra-abdominal injury is very strongly suspected
2. Clear and persistent signs of peritoneal irritation
3. Radiologic evidence of pneumoperitoneum consistent with a viscus rupture
4. Evidence of a diaphragmatic rupture
5. Persistent, significant gastrointestinal bleeding seen in the nasogastric return or in vomitus

Establishing the need for urgent laparotomy on clinical grounds is particularly problematic in the patient with multiple blunt injuries. Numerous extra-abdominal potential sources of hypotension exist. In addition, there is often coincident head injury or intoxication to further impair the reliability of examination. A

www.ketabpezeshki.com 66485457-66963820

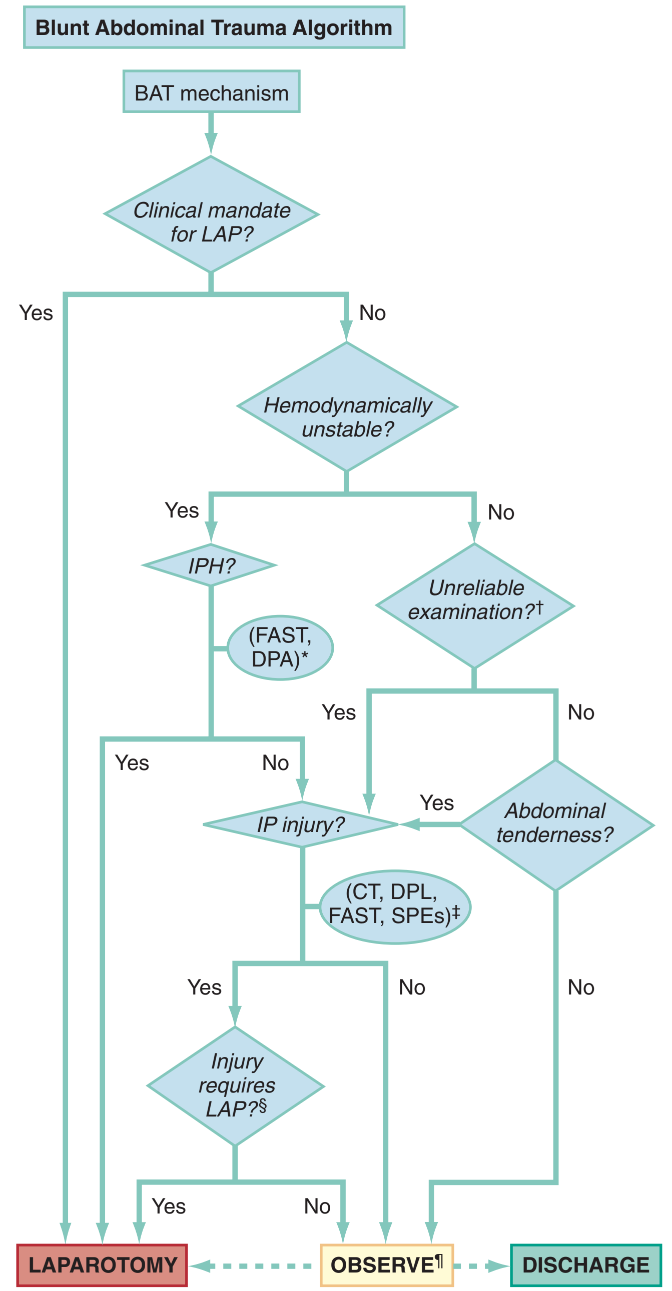

Figure 46-12. Blunt abdominal trauma (BAT) algorithm. *CT,* computed tomography; *DPL,* diagnostic peritoneal lavage; *FAST,* focused assessment with sonography in trauma; *IP,* intraperitoneal; *IPH,* intraperitoneal hemorrhage; *LAP,* laparotomy; *SPEs,* serial physical examinations.
*Determined by unequivocal free intraperitoneal fluid on FAST or positive aspiration of blood on diagnostic peritoneal aspiration (DPA).
†Can be unreliable because of closed head injury, intoxicants, distracting injury, or spinal cord injury.
‡One or more studies may be indicated.
§Need for laparotomy is based on clinical scenario, diagnostic studies, and institutional resources.
¶Duration of observation should be 6 to 24 hours depending on whether diagnostic tests have been performed, the results of the tests, and clinical circumstances, including the absence of factors rendering the examination unreliable.

nontherapeutic laparotomy may imperil the patient, not so much because of the potential morbidity of the procedure but rather because more vital diagnostic and therapeutic steps are delayed. When confusion exists, corroborative diagnostic tests are strongly preferred.

Table 46-5 Clinical Indications for Laparotomy after Blunt Trauma

MANIFESTATION	PITFALL
Unstable vital signs with strongly suspected abdominal injury	Alternate sources of shock
Unequivocal peritoneal irritation	Potentially unreliable
Pneumoperitoneum	Insensitive; may be caused by cardiopulmonary source or invasive procedures (diagnostic peritoneal lavage, laparoscopy)
Evidence of diaphragmatic injury	Nonspecific and insensitive, especially in penetrating trauma
Significant gastrointestinal bleeding	Uncommon, unknown accuracy

Hemodynamically Unstable Patients. In the patient with multiple blunt injuries who is threatened by shock, three cavities are immediately targeted. Chest and pelvic radiographs seek blood loss in the thoracic and retroperitoneal spaces, respectively. FAST or peritoneal aspiration is undertaken to reveal or exclude the presence of blood in the peritoneal cavity. Hemoperitoneum in a clinically unstable patient necessitates laparotomy.

Hemodynamically Stable Patients. In patients who are hemodynamically stable, CT scanning is the widely preferred diagnostic modality because of its ability to specify organ pathology, semiquantitate hemoperitoneum, and study nonabdominal body regions. Its potential drawbacks in certain clinical circumstances must be understood, however. Ultrasonography, DPL, and, very uncommonly, laparoscopy can be used in a complementary or primary mode.

Operative versus Nonoperative Management. Patients with certain intraperitoneal injuries can be watched expectantly and need not be subjected to laparotomy. Specifically, this has been successful with even moderate- to high-grade liver or spleen trauma. Failures, including deaths, have occurred with this approach. Thus, although it is preferable to avoid unnecessary laparotomy, it is imperative to prevent significant morbidity or mortality by waiting too long. The patient with normal sensorium and minor to intermediate severity of mechanism is a superior candidate for expectant management. It is critical that an institution appraise its ability to manage such patients. This includes having experienced nursing staff, trauma surgeons, adequate blood resources, and radiologists and the ability to take a patient to undergo laparotomy urgently if the need arises.

Several pitfalls in the expectant approach are noteworthy. First, multiple injuries of intraperitoneal organs, including hollow viscera, are common.[72] Operative management of hollow visceral injury is necessary, and delay can have severe consequences.[114] The ability of the CT scan to detect coincident injury to these structures is discussed earlier. The patient with multisystem injury and, specifically, closed head trauma is most vulnerable to having delayed diagnosis of perforated intestinal injury.[72,74] Second, expectant management may lead to increased use of blood products. Finally, this management approach will fail in those patients whose hemorrhage is not amenable to therapeutic angiography and embolization and will not abate because of misperceived injury of solid organs. In such cases, the lag time from injury to operation may increase morbidity and mortality.[115]

Pelvic Fracture. In the setting of pelvic fracture, the clinical triage determinant is the presence or absence of hemoperitoneum (Fig. 46-13). Although the sensitivity of FAST in patients with pelvic fractures is decreased, it still serves as a tool to triage the patient to the next intervention. In an unstable patient, a negative

www.ketabpezeshki.com 66485457-66963820

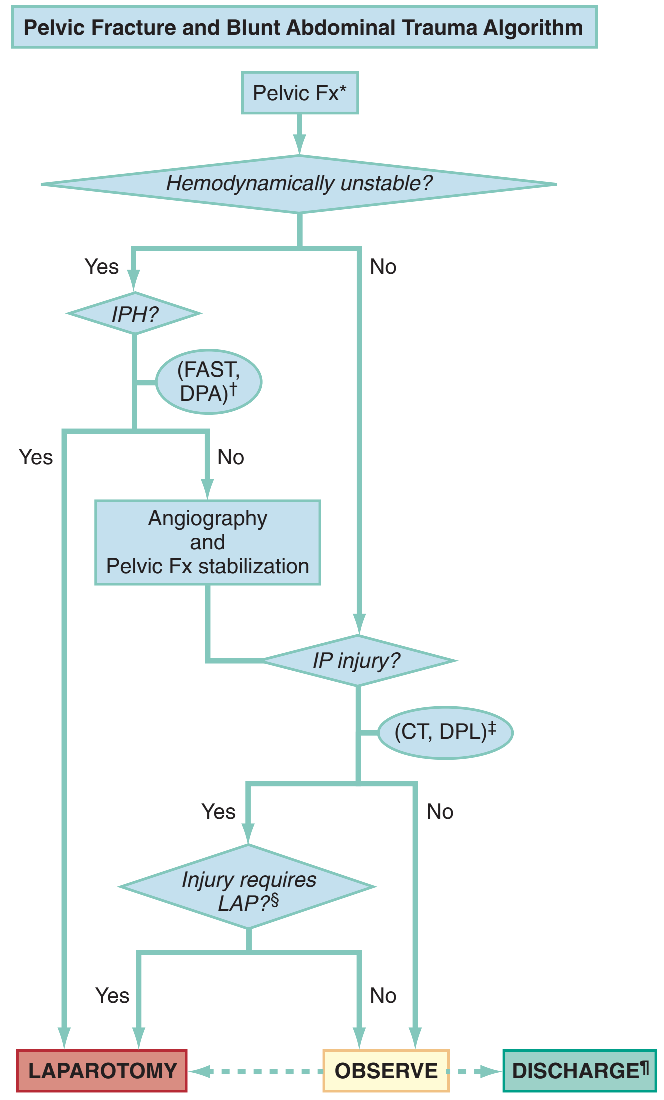

Figure 46-13. Pelvic fracture (Fx) and blunt abdominal trauma algorithm. *CT,* computed tomography; *DPL,* diagnostic peritoneal lavage; *FAST,* focused assessment with sonography in trauma; *IP,* intraperitoneal; *IPH,* intraperitoneal hemorrhage; *LAP,* laparotomy.
*Certain pelvic fractures are more likely to cause pelvic vascular disruption and subsequent retroperitoneal hemorrhage.
†Determined by unequivocal free intraperitoneal fluid on focused assessment with sonography in trauma (FAST) or positive peritoneal aspiration on diagnostic peritoneal aspiration (DPA).
‡One or more studies may be indicated. Serial physical examinations are generally considered unreliable owing to the presence of pelvic fracture.
§Need for laparotomy is based on clinical scenario, diagnostic studies, and institutional resources.
¶Discharge from the perspective of need for further consideration for laparotomy.

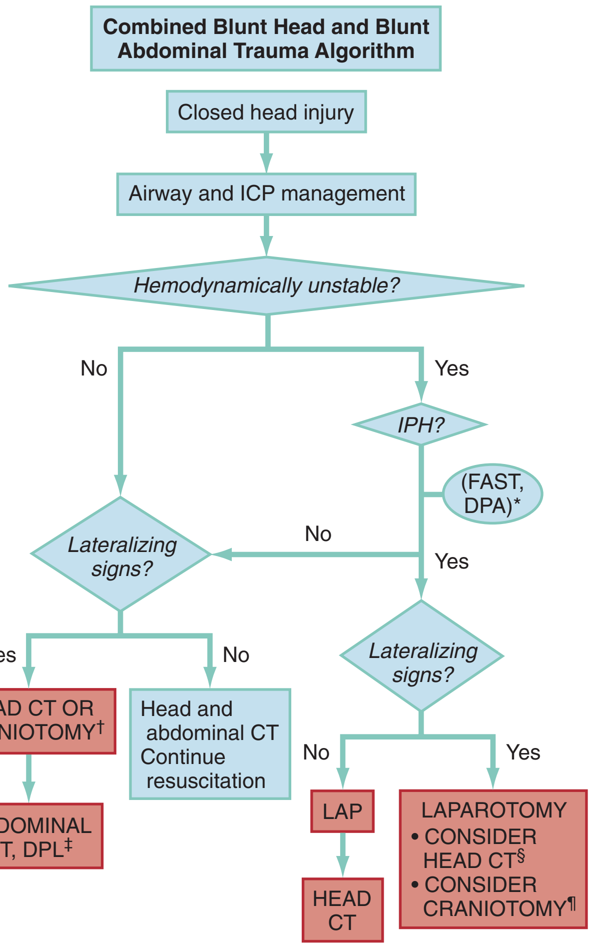

Figure 46-14. Combined blunt head and blunt abdominal trauma algorithm. *CT,* computed tomography; *ICP,* intracranial pressure; *IPH,* intraperitoneal hemorrhage.
*Determined by unequivocal free intraperitoneal fluid on focused assessment with sonography in trauma (FAST) or positive peritoneal aspiration on diagnostic peritoneal aspiration (DPA).
†Craniotomy or burr holes based on clinical picture and unavailability of computed tomography (CT).
‡Diagnostic peritoneal lavage (DPL) can be complementary to CT in determining hollow viscus injury.
§Consider prelaparotomy (LAP) head CT based on clinical picture and availability of CT.
¶Consider craniotomy or burr holes simultaneous with laparotomy.

FAST is followed by a supraumbilical peritoneal aspirate, to avoid potential false positives caused by retroperitoneal blood moving to the anterior infraumbilical space. If this reveals 10 mL or more of blood, then the patient should expeditiously be moved to laparotomy. If instead urine or other fluid is aspirated, then the patient should undergo pelvic angiography before laparotomy. If the FAST is negative, then the patient should proceed to therapeutic angiography with the presumed diagnosis of a life-threatening retroperitoneal bleed. In stable patients, early mechanical pelvic stabilization is advised (see Chapter 55), and CT scan followed by pelvic angiography and embolization are undertaken as early as possible in the context of the multiple injuries.

Multiple System Injury. Management of the abdominal trauma patient with more than one life-threatening injury cannot be dogmatic. It is not unusual to confront intraperitoneal hemorrhage in a patient with apparent closed head injury or suspected blunt aortic disruption or both. Repair of the abdomen is said to take precedence over that of the head and chest. However, these situations are highly complex, and decision-making is influenced by numerous and dynamic variables. The key tenet is that a patient with known hemoperitoneum whose vital signs cannot be stabilized should undergo laparotomy or face imminent exsanguination.

Closed head Injury. In general, patients with coincident severe closed head injury but without frank coma or lateralizing signs do not have intracranial lesions that require craniotomy. When lateralizing features do exist, the clinician must choose between a rapid prelaparotomy CT scan of the head or preemptive burr holes at laparotomy. This judgment rests mostly on the clinical state of the patient with particular regard to his or her response to resuscitative measures and the timely availability of CT.[116] An approach to this scenario is presented in Figure 46-14.

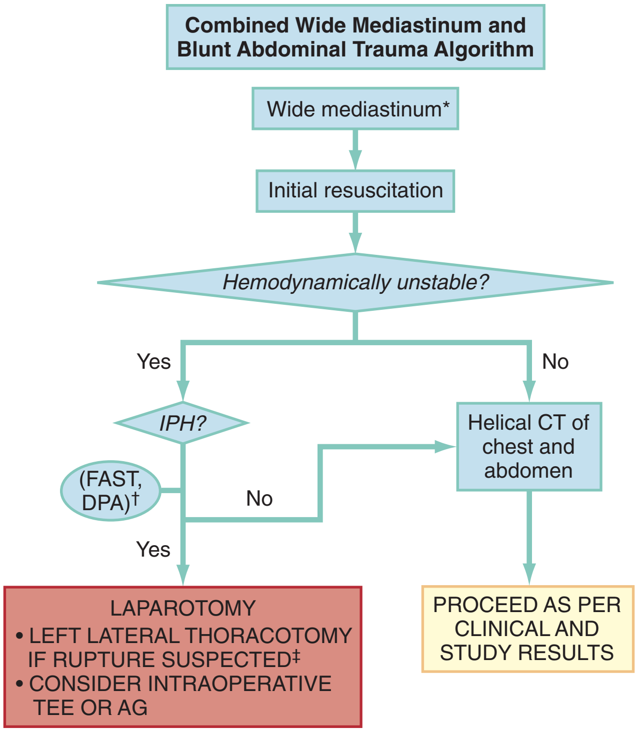

Figure 46-15. Combined wide mediastinum and blunt abdominal trauma algorithm. *AG,* aortogram; *CT,* computed tomography; *FAST,* focused assessment with sonography in trauma; *IPH,* intraperitoneal hemorrhage; *TEE,* transesophageal echocardiogram.
*Preferably based on upright posteroanterior film and mechanism of injury; other radiographic signs or mechanism alone may signal need for evaluation.
†Determined by unequivocal free intraperitoneal fluid on FAST or positive finding on diagnostic peritoneal aspiration (DPA).
‡Allows surgical access to majority of aortic disruption sites.

Blunt Aortic Injury. Clinical or radiographic features that portend great vessel injury, notably a widened mediastinum on a supine anteroposterior chest radiograph, have variable sensitivity and specificity. In addition, although the course of any single aortic lesion is unpredictable, there is more likely than not a lag of at least several hours before rupture. Therefore exigent laparotomy should precede great vessel diagnostics. Should the patient's condition precipitously deteriorate, left lateral thoracotomy allows aortic cross-clamp with its circulatory benefits and, in general, affords access to the injured portion of the vessel (Fig. 46-15).

Pediatrics. Children are prone to aerophagia, and decompressive nasogastric tubes are particularly important to help prevent compromised lung function and aid in the abdominal examination. Care is taken in fluid resuscitation and drug administration, with attention being paid to the patient's size and with surface area or body weight used as a guide. Because of their size and relatively larger surface area, children are more susceptible to hypothermia resulting from the administration of unwarmed fluids and blood products. The use of overhead heat lamps, blood warmers, and prewarmed intravenous fluids helps obviate this condition.

Children with major injuries may cause fear and anxiety in even the most experienced emergency physician or surgeon. It is imperative to maintain careful vigilance and overcome any tendency to avoid indicated procedures.

For physiologic reasons, the expectant management of blunt hepatic or splenic injury has better success in the child than in the adult patient.[117-119] If stability exists, nonoperative management can ensue if capable personnel and resources are present.[120] CT scanning is the primary diagnostic agent in both the initial and the convalescent periods to define and grade solid organ injury. As for adults, this modality is insensitive for the discovery of hollow viscus and, to a lesser degree, pancreatic pathologic conditions.[71]

FAST has been found to be useful for the detection of free fluid and can be used in triage to send the unstable child with visualized hemoperitoneum for laparotomy.[121] However, FAST appears to have less sensitivity when compared with the adult experience. DPL, specifically peritoneal aspiration, can also uncover hemoperitoneum in the initial management of the critically, multiply injured child. Reliance on cell count alone has prompted significant nontherapeutic laparotomy rates.

In the course of expectant treatment, the child should undergo laparotomy if instability develops, transfusion requirements are excessive, peritoneal signs are unequivocal, or observation is not feasible because of associated injuries or lack of institutional resources. Closed head injury need not preclude nonoperative management of known solid parenchymal injury, but the risk associated with undiscovered and coincident hollow viscus perforation is greatly increased. The diagnostic approach to penetrating trauma in children is the same as that in adults.

Transfer. Trauma patients in rural settings may require a stabilizing damage control laparotomy by a general surgeon before being transferred to a trauma center for definitive care.

KEY CONCEPTS

- The accuracy of physical examination is limited in cases of blunt and penetrating trauma. It is rendered less reliable by distracting injury, altered sensorium (e.g., head trauma, alcohol or drug intoxication, developmental delay, psychiatric illness), and spinal cord injury.
- Implements and missiles frequently violate the lung parenchyma, diaphragm, mediastinum, intraperitoneal cavity, and retroperitoneum in some combination.
- The choice of diagnostic studies for abdominal trauma is based on clinical need first and foremost, as well as study availability and the accuracy of that study in a respective center.
- FAST and peritoneal aspiration are rapid methods of determining or excluding the presence of hemoperitoneum in the critically ill blunt or penetrating trauma patient. DPL is more sensitive but is invasive and therefore rarely used. FAST is noninvasive and can simultaneously evaluate for hemopericardium and pneumothorax and hemothorax.
- Clinical indications for laparotomy are more dependable in and more frequently applicable to cases of penetrating trauma than cases of blunt trauma.
- The critical determinant in hemodynamically unstable patients with pelvic fracture is the existence of active intraperitoneal hemorrhage. Discovery of this by FAST, CT scan, or peritoneal aspiration is an indication for laparotomy, whereas its absence prompts diagnostic and potentially therapeutic angiography.

Chapter 47

Genitourinary System

Michael S. Runyon

PERSPECTIVE

Despite considerable advances in the initial evaluation and management of the severely injured patient, confusion remains regarding the recognition and subsequent management of genitourinary trauma. Only major renovascular injuries or a severely shattered kidney, both of which are rare, portend a rapid death. Thus most genitourinary injuries pale in comparison with the potential immediate life threats posed by concomitant injuries to the head, chest, and abdomen. The urinary tract as an anatomically injured system is by necessity relegated to a position of secondary importance. Nevertheless, to maintain clinical excellence and expertise in the overall treatment of all injured patients, the emergency physician should have a thorough understanding of the global spectrum of genitourinary injury and how it can affect patient outcomes.

Genitourinary trauma is frequently a covert entity and is associated with a wide array of injury. Approximately 10% of all multiply injured patients have some manifestation of genitourinary involvement.[1] Because of its relatively infrequent occurrence and often subtle presentation, it may be overlooked in the initial evaluation of the multiply injured patient. Prompt identification and appropriate management of genitourinary injuries can minimize potential long-term complications, including renal insufficiency, chronic hypertension, incontinence, and sexual dysfunction. The astute emergency physician can accomplish these goals by a stepwise evaluation that considers the mechanism of injury, pertinent physical examination findings, urinalysis, and adjunctive diagnostic imaging.

For the stable patient, the urinary tract is unique in that diagnostic evaluation is done in a retrograde fashion—that is, clinical suggestion and elimination of urethral injury before bladder injury before ureteral or renal injury. Adherence to this axiom enables the discovery of virtually any important urinary tract injury. Deviations from this practice may be necessary when life-threatening renal injuries are suspected.

Definitions

For purposes of investigation and staging of urologic injuries, genitourinary trauma is divided into lower tract (bladder or urethral injury), upper tract (renal or ureteral injury), and external genitalia (penile, scrotal, testicular, and vulvar injury). Each category is further subdivided on the basis of a blunt or penetrating mechanism of injury.

Historical Perspective

The basic tenets of lower urinary tract injury have not changed appreciably in recent decades. A thoroughly performed physical examination, pelvic radiography, and the recognition of gross hematuria or blood at the urethral meatus identify virtually all significant lower urinary tract injuries. Major advances in the identification of significant upper tract genitourinary injuries, their clinical markers, and ultimate staging procedures have come to the forefront over the last few decades. Before 1985, all trauma patients with any amount of microhematuria were labeled "at risk" for genitourinary injury and underwent intravenous pyelography. This was neither diagnostically definitive nor cost-effective and simply perpetuated the existing confusion and controversy. In 1985, Nicolaisen and colleagues published the first of a series of articles that established guidelines for identifying significant upper tract genitourinary injuries, their markers, and the diagnostic studies that define the exact extent of these injuries and aid in subsequent patient management.[2] In addition, the advent of ultrasonography has greatly simplified the diagnosis and management of external genitalia trauma.

CLINICAL FEATURES

The symptoms, signs, and examination findings of genitourinary trauma are varied and nonspecific. Acutely, these may include flank, abdominal, rib, back, pelvic, or scrotal pain; urinary retention; penile or scrotal ecchymosis or hematoma; and blood at the urethral meatus. Renovascular hypertension, incontinence, or sexual dysfunction may be the only findings weeks to months after injury.

Physical Examination

Examination of the torso and pelvis during the secondary survey is the first step in the evaluation for urologic injury. Any evidence of abdominal tenderness or low anterior pelvic injury should alert the examining physician to the possibility of a bladder rupture in addition to other intra-abdominal injuries. This likelihood increases significantly in the presence of a pelvic fracture. Tenderness elicited by pelvic compression or palpation of the pelvic girdle or pubic symphysis supports the diagnosis of a potential pelvic fracture and the possibility of lower urinary tract injury.

Examination of the genitalia can be informative. The emergency physician should examine for evidence of hematoma or

www.ketabpezeshki.com 66485457-66963820

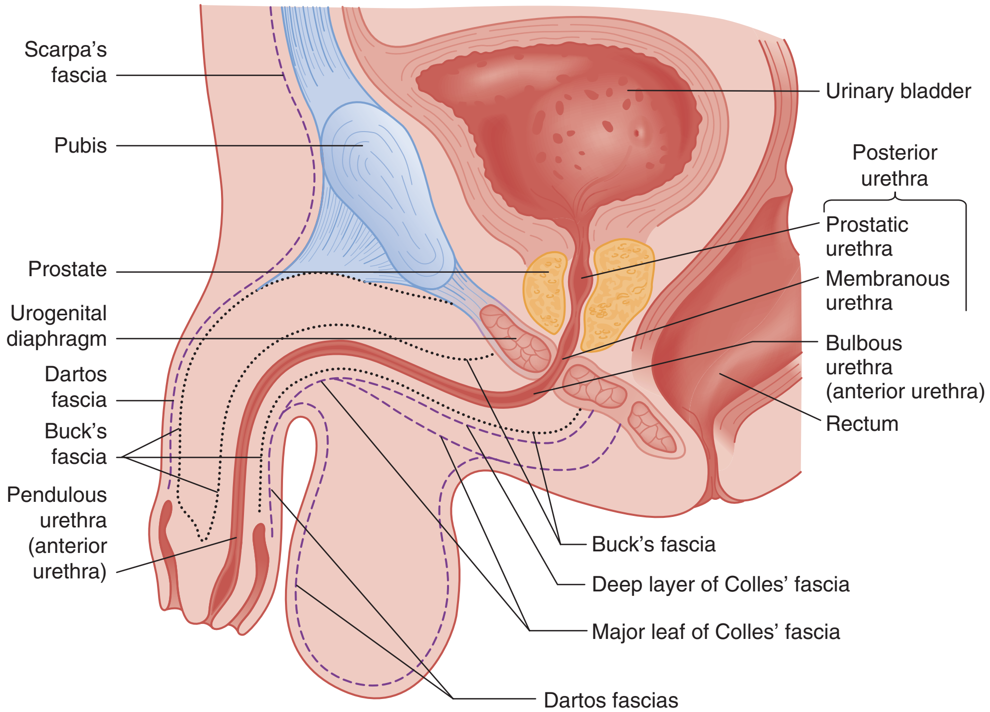

Figure 47-1. Anatomy of male genitalia.

ecchymosis of the penile shaft, scrotal skin, or perineum. Gross blood at the urethral meatus is suggestive of a urethral injury and suggests the need for retrograde urethrography. In circumstances in which emergency surgical exploration for life-threatening injuries is indicated, retrograde urethrography can be performed in the operating room or after the operative procedure. For the male patient, classic teaching dictates that a Foley catheter should never be introduced when urethral injury is possible without prior evaluation of urethral integrity by retrograde urethrography. The concern is that trauma from the catheter placement may convert a partial urethral tear into a complete disruption. Although the literature on this topic is sorely lacking, one small retrospective review of 13 cases of urethral injury demonstrated no evidence that a careful blind attempt to insert a urinary catheter worsened the initial injury.[3]

Careful inspection for blood at the vaginal introitus is particularly important in the female patient known to have a pelvic fracture. A vaginal examination can discern vaginal lacerations or urethral disruption caused by displaced bony pelvic fracture fragments. This examination should be conducted carefully so as to protect the hands of the examiner from injury as well as to prevent worsening of the injuries themselves. Urethral injuries are uncommon in female patients owing to the short length and increased mobility of the female urethra and the relative protection from injury afforded by the symphysis pubis. Unlike with male urethral injuries, urethrography is technically difficult and not routinely recommended in females with suspected urethral injury. The inability to pass a Foley catheter in a premenopausal female patient with a pelvic fracture signifies the potential for urethral injury and possible need for suprapubic urinary drainage. Successful passage of a Foley catheter in a patient with blood at the vaginal introitus does not exclude urethral injury, however, and these worrisome physical examination findings are conveyed to the urologist, who can plan subsequent endoscopic or radiographic urethral evaluation accordingly.[4-6] In an older postmenopausal female trauma patient, urethral injury is distinguished from a superiorly retracted urethral meatus and accompanying meatal stenosis. These preexisting conditions are common in an atrophic vaginal setting, and a 12- or 14-Fr coudé or Foley catheter usually is required to achieve successful bladder access.

The digital rectal examination evaluates sphincter tone, bowel wall integrity, the presence or absence of gross blood, and the position of the prostate. Normally the posterior lobe of the prostate is palpable and well defined (Fig. 47-1). A pelvic fracture may disrupt the puboprostatic ligaments and the prostatomembranous urethra, resulting in significant retropubic venous bleeding. This may produce a large pelvic hematoma that can displace the prostate superiorly, resulting in a boggy, ill-defined mass on rectal examination (Fig. 47-2). Although it has long been recommended as part of the routine evaluation of all trauma patients, multiple studies have questioned the utility of the rectal examination in this setting and have specifically demonstrated that a palpably abnormal prostate is an insensitive indicator of urethral injury.[7-10] Thus the decision to evaluate for urethral injury should consider additional clinical features, especially the presence or absence of gross hematuria or blood at the urethral meatus, and not rely on the findings of the rectal examination.

Foley Catheter

In any significantly injured trauma patient with a major mechanism of injury and the absence of any findings suggestive of urethral injury, a Foley catheter should be passed into the bladder. The initial bladder effluent should be observed by the physician. Because of its importance in dictating subsequent patient evaluation, gross hematuria is conservatively defined as any color to the urine other than clear or yellow. The presence of gross hematuria indicates urologic injury until proven otherwise. Rarely, severe rhabdomyolysis produces large quantities of urine myoglobin, the gross appearance of which can be confused with gross hematuria. In these cases, urinalysis documents the absence of red blood cells (RBCs) consistent with myoglobinuria. Most significant lower urinary tract injuries are accompanied by a pelvic fracture, blood at the urethral meatus, or gross hematuria on spontaneous voiding or Foley catheter placement. However, injuries to the upper tract tend to be more subtle. They are often coincident with

www.ketabpezeshki.com 66485457-66963820

nonurologic organ disruption, the bleeding from which can be life-threatening. These events may dictate rapid volume resuscitation that can clear gross hematuria quickly. Moreover, some significant upper tract injuries, including blunt injury to the renovascular pedicle or penetrating ureteral injury, may not produce gross or even microscopic hematuria.

LOWER URINARY TRACT

URETHRAL TRAUMA

Anatomy

The urogenital diaphragm divides the anterior (bulbous and pendulous) urethra from the posterior (membranous and prostatic) urethra. Contrary to early descriptions, the urogenital diaphragm does not completely encircle the membranous urethra, but rather forms an incomplete sling that offers posterior and lateral support.[5] The prostatic urethra is attached to the posterior symphysis pubis by the puboprostatic ligaments. A fracture of the pelvis with displacement of the symphysis may result in a laceration or avulsion of the prostatic urethra because of the shearing force on the fixed prostatic and membranous urethra. Injuries to the anterior and posterior urethra are caused by different mechanisms, involve different symptoms, and are treated differently.

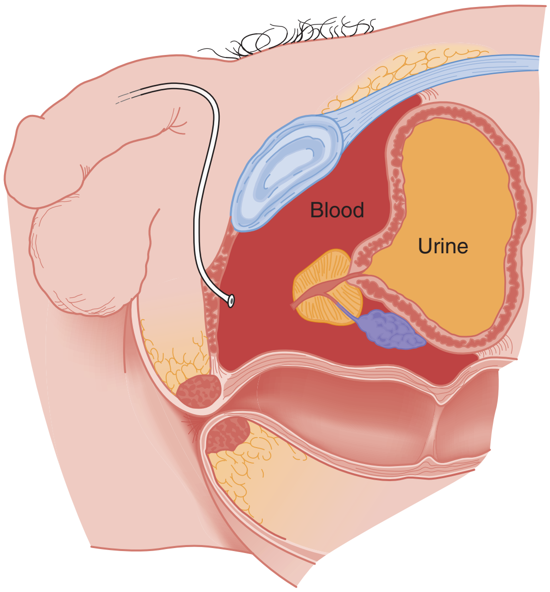

Figure 47-2. Injury to the posterior (membranous) urethra. The prostate has been avulsed from the membranous urethra secondary to fracture of the pelvis. Extravasation occurs above the triangular ligament and is periprostatic and perivesical. (From McAninch JW: Injuries to the Genitourinary Tract. In Tanagho EA, McAninch JW [eds]: Smith's General Urology, 14th ed. Norwalk, Conn, Appleton & Lange, 1995.)

Pathophysiology

Urethral disruption is the most significant injury to be identified. Failure to do so may lead to significant morbidity. Overly aggressive urethral manipulation can convert a partial urethral tear into a complete tear, thus precluding accurate assessment of urinary output and subsequently potentiating the long-term complications of urethral trauma (e.g., urethral stricture formation and urinary incontinence). Anterior urethral injuries are most often caused by straddle injuries, falls, gunshot wounds, and self-instrumentation (Fig. 47-3).

Pelvic fractures account for most posterior urethral injuries (see Fig. 47-2). The risk of urethral injury varies with the specific type of pelvic fracture. High-risk fractures include the straddle fracture, in which all four pubic rami are involved, and the Malgaigne fracture, which involves fracture and displacement of the hemipelvis—that is, both ischiopubic rami anteriorly and the ipsilateral sacrum, sacroiliac joint, or ilium posteriorly. Urethral injuries are rarely associated with fractures that do not involve the ischiopubic rami.[5,11] In a prospective, single-center study of 203 consecutive male patients with pelvic fractures, 51 sustained urethral injuries. Malgaigne and straddle fractures were significantly associated with urethral injuries, with odds ratios of 3.4 and 3.85, respectively. In the same series, the highest risk for urethral injury was seen in patients sustaining a straddle fracture with concurrent sacroiliac diastasis (odds ratio 24). Among those sustaining fractures not involving the anterior pelvic arch, none had urinary tract injury.[11]

Clinical Features

During the secondary survey, examination of the lower abdomen, pelvis, and genitalia provides both direct and indirect evidence to support or refute urethral injury. Urethral integrity is supported by lack of pelvic and suprapubic tenderness; absence of penile,

scrotal, or perineal hematoma; and lack of blood at the urethral meatus. These physical findings permit the safe passage of a 14- or 16-Fr Foley catheter into the bladder if the patient is unable to void and provide a suitable specimen for evaluation.

Diagnostic Strategies

Catheter Placement

The following technique for catheter placement assumes a normal urethra and includes the use of sterile technique, proper control of the foreskin, the use of copious amounts of lubricating jelly, and the gentle passage of a 14- or 16-Fr Foley or coudé catheter into the bladder. In all uncircumcised patients, continuous foreskin retraction with a folded 4 × 4-inch gauze pad is necessary to control the foreskin during catheter placement (Fig. 47-4). Without

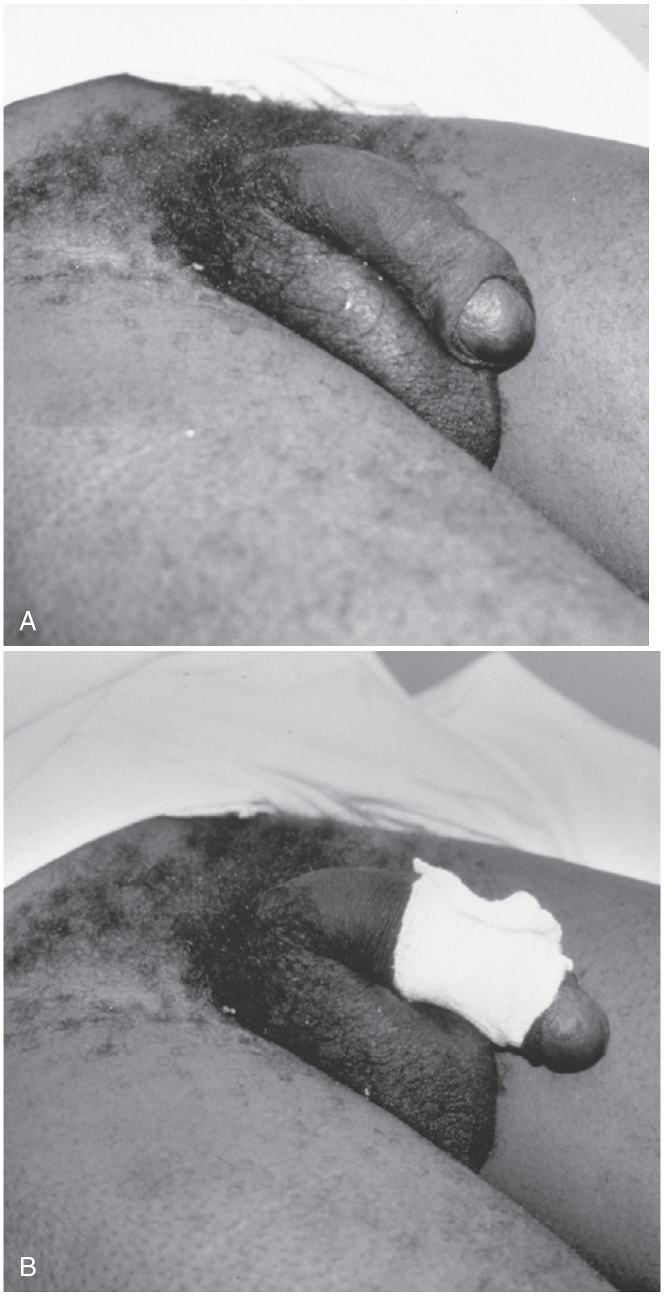

Figure 47-4. **A,** A normal uncircumcised man. **B,** Foreskin has been retracted and a folded 4 × 4-inch gauge sponge wrapped around it to prevent foreskin reduction during instrumentation.

this maneuver, the foreskin tends to repeatedly reduce itself over the glans penis, which contaminates the field and complicates the catheterization attempt. Slight resistance to the advancing catheter should be expected secondary to voluntary contraction of the external sphincter. This is more apt to occur in a combative, anxious trauma patient than in a cooperative or unconscious patient. When this occurs, the patient should be reassured and asked to relax the perineum and rectal area while gentle advancing pressure is applied to the catheter. This combined approach allows the catheter to navigate the external sphincter successfully and pass easily into the bladder. If reassurance and relaxation do not allow easy passage of the catheter in a male patient with clinical features suggestive of urethral injury, it should be removed and retrograde urethrography performed. The catheter is passed to its fullest extent to ensure that the balloon is completely in the bladder when inflated, The catheter is then withdrawn to the point of balloon approximation with the bladder neck, secured to the patient's leg to prevent accidental dislodgement, and left to drain. Inflation of the catheter balloon under any other circumstances may result in iatrogenic urethral trauma.

Successful passage of a Foley catheter precludes a complete urethral disruption. Nonetheless, the possibility of a partial urethral injury not manifested by history, mechanism of injury, or physical examination does exist. If a possible urethral injury is suggested by physical examination findings before the placement of a Foley catheter, a retrograde urethrogram should be obtained. The presence of urethral extravasation together with contrast material filling the bladder is diagnostic of a partial urethral injury (Fig. 47-5). Identification of a partial urethral injury enables one careful attempt at urethral placement of a 12- or 14-Fr Foley or coudé catheter, depending on the size of the patient.[6] If any difficulty is encountered, the catheter should be removed and a urologist consulted. If a partial urethral tear is suggested subsequent to successful passage of a Foley catheter, a small feeding tube can be placed alongside the urethral catheter and a modified retrograde urethrogram obtained. In this circumstance the urethrogram is for documentation and subsequent management purposes only because appropriate therapy (Foley catheter drainage) has already been instituted.

Radiology

In male patients with possible urethral injury, retrograde urethrography is the diagnostic procedure of choice. Retrograde

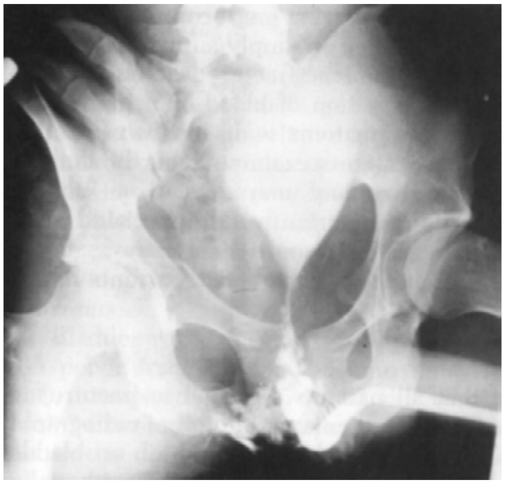

Figure 47-5. Retrograde urethrogram demonstrates a partial urethral disruption. Note the elongation of the posterior urethra with filling of the bladder. (From Spirnak JP: Pelvic fracture and injury to the lower urinary tract. Surg Clin North Am 68:1057, 1988.)

www.ketabpezeshki.com 66485457-66963820

urethrography is not an emergency procedure and should follow more critical diagnostic and resuscitative measures.

In a patient with a pelvic fracture, the entire retrograde urethrogram should be obtained with the patient in the supine position. Although some authors recommend oblique films for portions of the retrograde urethrogram to enhance urethral definition, these views add little information to a good supine study. More important, pelvic fractures are often associated with significant venous bleeding and hematoma formation. Maintenance of this stable hematoma can be crucial in the initial hemodynamic resuscitation of the patient. Any patient movement from the supine to the oblique position has the potential to disrupt the organized hematoma with resultant significant and potentially lethal rebleeding. The integrity of the entire urethral length can be defined with the patient in the supine position throughout the examination, aided by oblique stretching of the penis over the left or right thigh to promote necessary urethral unfolding.

A preinjection kidney, ureter, and bladder (KUB) film is first obtained. In uncircumcised patients, the penile foreskin is retracted and secured with a folded 4 × 4-inch gauze pad (see Fig. 47-4). The penis should be held between the long and ring fingers of the nondominant hand. A simple Christmas tree adapter, a Cooke adapter placed on the end of a 60-mL Toomey syringe, or a Toomey syringe alone is gently passed into the urethral meatus until a snug fit inside the meatus is confirmed. The distal end of the syringe is secured with the thumb and index fingers of the nondominant hand (Fig. 47-6). Some authors have recommended inflation of a Foley catheter balloon just proximal to the fossa navicularis or the use of other cumbersome adjuncts to facilitate injection of contrast media. These techniques should be avoided, however, because they promote leakage of contrast material around the penis, which can simulate extravasation on the urethrogram and promote a spurious examination. Next, 60 mL (or 0.6 mL/kg in children) of full-strength or half-strength water-soluble contrast medium is injected slowly over 30 to 60 seconds. Overly forceful injection may result in intravasation of contrast material into the urethral venous plexus. A radiograph is taken during the injection of the last 10 mL of contrast material. Retrograde flow through the urethra and into the bladder without extravasation ensures continuity of the urethra and absence of urethral injury (Fig. 47-7). Extravasation of contrast material outside the urethra with concomitant evidence of bladder filling distinguishes a partial urethral injury (see Fig. 47-5) from a complete urethral disruption, in which contrast material will be absent from inside the bladder (Fig. 47-8). The latter situation requires urologic consultation for appropriate management, the timing and specifics of which remain controversial and depend on the location and mechanism of injury.[6,12,13] In the interim, if measurement of urinary output is essential, the bladder should be accessed by the suprapubic placement of a peel-away sheath and Foley catheter through use of the Seldinger technique (Fig. 47-9). When venous intravasation of contrast is suggested, a postvoid film demonstrates clearing of any intravasated material while extravasated contrast from a urethral injury remains. Retrograde urethrography should be deferred if pelvic angiography is indicated, as extravasated contrast material from a urethral injury may obscure computed tomography (CT) scans and angiographic images and

complicate attempts to control significant pelvic hemorrhage by vascular embolization.[14]

Management

If the clinical features of urethral injury are absent or the urethrogram is normal, the urethra is intact and a Foley catheter can be passed into the bladder. If a partial urethral disruption is identified, one careful attempt to pass a 12- or 14-Fr Foley or coudé catheter can be undertaken. If this is unsuccessful or if a complete urethral tear is detected, placement of a suprapubic catheter for measurement of urinary outflow and volume requirements is often needed, especially if the patient is in shock or requires osmotic therapy for a severe head injury.

The optimal definitive management of urethral injuries remains a subject of controversy in the urologic literature.[6,12,13] Pertinent variables include the location of the injury (anterior vs. posterior), extent of the disruption (partial vs. complete), mechanism of injury, hemodynamic stability of the patient, and presence of associated injuries. Treatment options vary from allowing a partial disruption to heal over a stenting urethral catheter to early or delayed, open or endoscopic repair. Adjunctive suprapubic urinary drainage is frequently indicated. Regardless of the specific management plan, the ultimate goals are the preservation of urinary continence and sexual function and avoidance of the disruption of any pelvic hematoma.

In female patients, proximal urethral injuries are managed by immediate surgical exploration and repair, as conservative management with proximal urinary diversion alone is associated with an increased risk of urethrovaginal fistulae or obliterative urethral strictures. Distal injuries may be managed by urethral catheterization. Regardless of the location of the urethral injury, associated

www.ketabpezeshki.com 66485457-66963820

vaginal lacerations require transvaginal repair to reduce the incidence of fistula formation.[6]

BLADDER TRAUMA

Anatomy

When empty, the bladder lies almost entirely within the bony pelvis. It rests on the pubis and adjacent pelvic floor parts. When full, the bladder can extend up to the level of the umbilicus, where it is most vulnerable to blunt and penetrating trauma. The bladder consists of an inner longitudinal, a middle circular, and an outer longitudinal muscle layer. These three layers constitute the detrusor muscle, which contracts to propel urine out the urethra. Blood is supplied to the bladder by the internal iliac artery and vein. The nerve supply comes from the lumbar and sacral segments of the spinal cord. It includes parasympathetic motor fibers to the detrusor muscle and sensory fibers to the detrusor that give rise to the sensation of fullness and urgency when the detrusor is stretched. Sympathetic fibers innervate the blood vessels of the bladder and the bladder neck musculature.

Pathophysiology

More than two thirds of bladder injuries result from blunt trauma. Approximately 90% result from motor vehicle collisions (MVCs) as a result of trauma sustained during ejection from the vehicle or the compressive force of the seat belt on a distended bladder. Approximately 80% of blunt bladder injuries are associated with fractures of the bony pelvis.[15] Additional life-threatening, nonurologic injuries are common and confer a significant mortality risk.[15,16] Penetrating injuries may be inflicted by gunshot wounds, stab wounds, or impalement injuries. The diagnostic evaluation of the bladder, like that of the urethra, can be accomplished quickly without elaborate radiographic equipment or can be part of the CT evaluation performed for the evaluation of nonurologic injuries.

Bladder injuries are classified as contusions, intraperitoneal ruptures, extraperitoneal ruptures, or a combination of intraperitoneal and extraperitoneal ruptures. Proper classification is important because treatment options differ with injury type. Intraperitoneal bladder rupture results from blunt lower abdominal trauma in a patient with a distended bladder. These blunt forces are directed to the dome of the bladder where the urachus originates during embryonic life. Because of this developmental hiatus, the dome is thinner and represents the anatomic area most susceptible to rupture from the sudden rise in intravesical pressure associated with blunt trauma. The dome also is unique in its isolated peritoneal reflection so that rupture in this area most likely results in intraperitoneal urinary contamination.

Extraperitoneal rupture occurs almost exclusively with pelvic fractures when the associated shearing forces result in tearing of the anterolateral bladder wall at its fascial attachments. Occasionally, extraperitoneal rupture results from bladder laceration by a bone spicule from the fractured pelvis.[15] Extravasated urine may be confined to the perivesical space or may dissect along tissue planes and extend to the penis, scrotum, thigh, anterior abdominal wall, obturator foramen, or retroperitoneum.[15,17,18]

Clinical Features

Lower abdominal or suprapubic pain, pelvic fracture, the inability to urinate, gross hematuria, or the presence of blood at the urethral meatus may alert the physician to the possibility of bladder injury.

Diagnostic Strategies

Laboratory

Gross hematuria is the cardinal sign of bladder injury and is present in more than 95% of cases.[15,19,20] In the setting of pelvic fracture, gross hematuria indicates the need to investigate for bladder injury. Relative indications for bladder imaging include gross hematuria without pelvic fracture and microhematuria in the setting of pelvic fracture.[15] Grossly clear urine in a blunt trauma patient without a pelvic fracture virtually eliminates the possibility of bladder rupture.

Radiology

Conventional retrograde cystography and retrograde CT cystography are the diagnostic procedures of choice for suggested bladder injury.[21-23] It is key that these studies *not* be done in an antegrade fashion, as such studies (e.g., injecting intravenous contrast material, clamping the Foley catheter, and allowing the examination to depend on antegrade filling of the bladder from renal excretion of progressively dilute contrast material) may produce incomplete and spurious findings owing to inadequate distention of the bladder.

Conventional Retrograde Cystogram. Performance of either conventional plain film retrograde cystography or CT retrograde cystography assumes prior evaluation of urethral integrity and the presence of an indwelling Foley catheter in the bladder. A Toomey syringe alone without its central piston is used for gravity instillation of contrast material (Fig. 47-10). Allowing the contrast material to freely infuse from a hanging bottle connected to an indwelling Foley catheter runs the risk of the tubing becoming disconnected, with contrast material subsequently leaking onto the examination table (Fig. 47-11A and B). This promotes an inaccurate examination that may result in an unnecessary operative procedure (Fig. 47-11C). In the setting of pelvic fracture, it is imperative that the patient remain supine throughout the examination. This lessens the potential for rebleeding from an organized retropubic hematoma.

A preliminary KUB or scout film is obtained to provide a baseline evaluation of the pelvis, abdomen, and surrounding bony structures. It will become the film of reference for the postevacuation radiograph obtained after completion of the cystogram. Potential areas of extravasation on the postevacuation film will be confirmed when compared with the preliminary KUB film (Fig. 47-12). Contrast material should not be instilled into the bladder

Figure 47-10. Retrograde cystogram. A Toomey syringe without its central piston is connected to the catheter and held by the examiner while gravity-instilled contrast material fills the bladder.

until the quality and anatomic information on the preliminary KUB film have been confirmed.

Full-strength water-soluble contrast medium is instilled under gravity filling to one of three endpoints:

1. Instillation of 100 mL with immediate fluoroscopic evidence of gross extravasation.
2. A total instillation of 300 to 400 mL in any patient 11 years of age or older; in patients younger than 11 years, the correct amount of contrast medium is determined by the following formula: (age in years divided by 2) × 30.
3. The instillation of a lesser amount than 100 mL that initiates a bladder contraction. This becomes evident by

www.ketabpezeshki.com 66485457-66963820

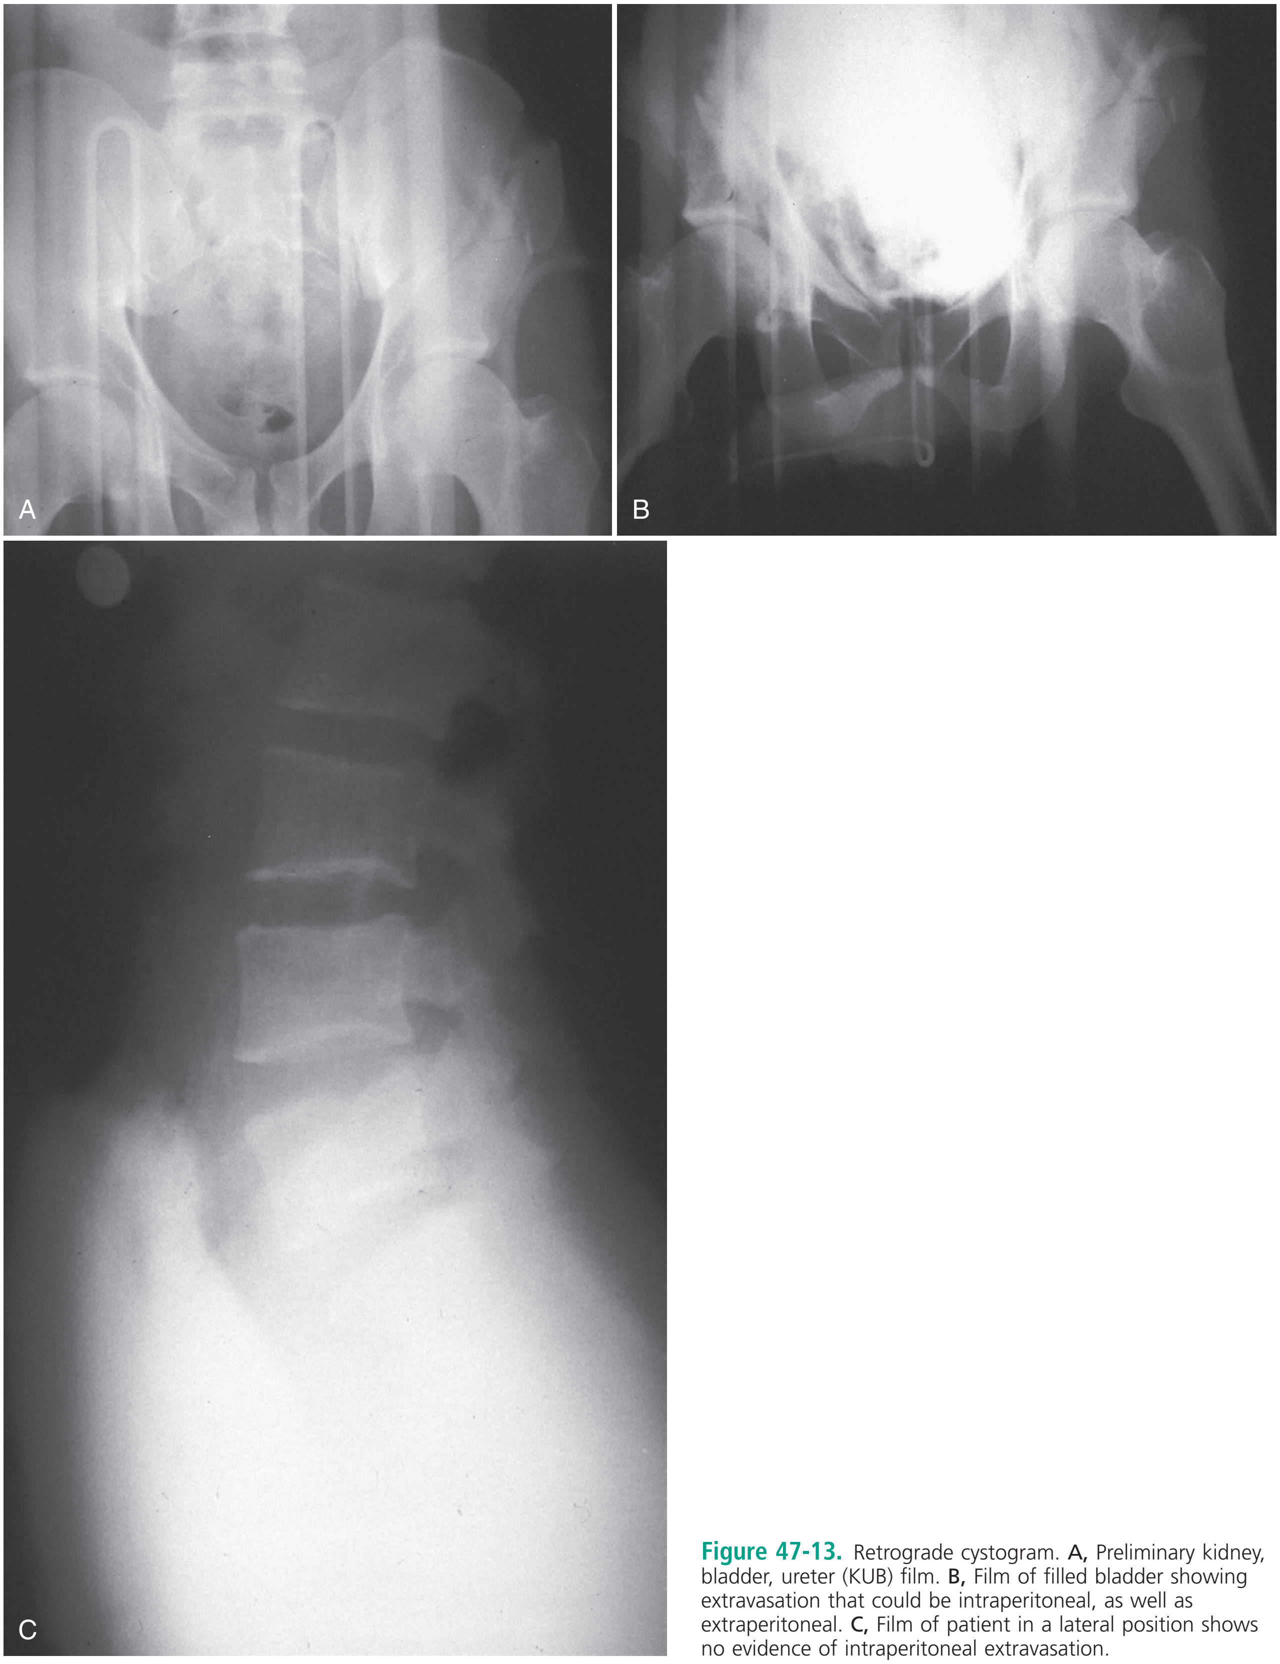

Figure 47-13. Retrograde cystogram. **A,** Preliminary kidney, bladder, ureter (KUB) film. **B,** Film of filled bladder showing extravasation that could be intraperitoneal, as well as extraperitoneal. **C,** Film of patient in a lateral position shows no evidence of intraperitoneal extravasation.

the retrograde filling of the Toomey syringe with bladder contents.

After a few minutes, the original contrast material can again be instilled to the point of stimulating a bladder contraction, at which time an additional 50 mL of full-strength contrast material should be injected slowly but forcefully into the bladder. The Foley catheter is clamped, and an anteroposterior radiograph is taken of the filled bladder (Fig. 47-13A and B). A lateral film may help clarify any areas in question (Fig. 47-13C). After the film of the filled bladder meets standards for quality and detail, the bladder should be completely evacuated into a large basin or, preferably, into an available bedside drainage bag. Any spillage

www.ketabpezeshki.com 66485457-66963820

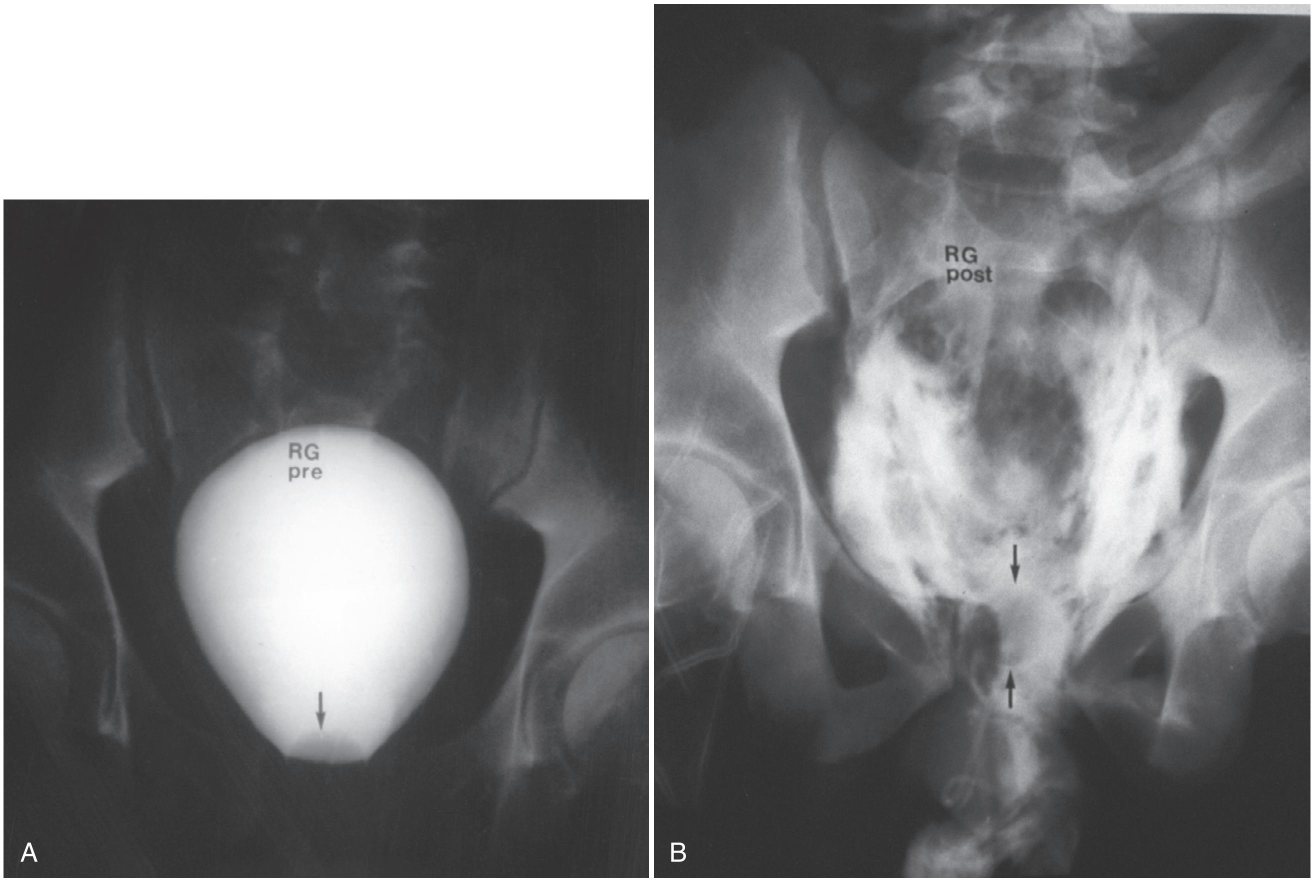

Figure 47-14. Retrograde cystogram. **A,** Film of filled bladder. **B,** Postevacuation film showing extensive extraperitoneal extravasation. Arrows point to the Foley catheter balloon.

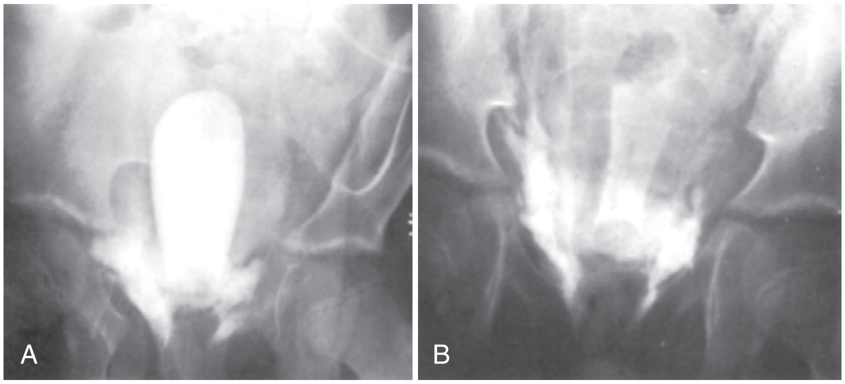

Figure 47-15. Cystographic appearance of extraperitoneal bladder perforation. Note the teardrop deformity caused by extrinsic compression by the pelvic hematoma and the flamelike wisps of extravasation confined by the pelvis. The bladder itself is elongated by a collection of perivesicular fluid. (From Spirnak JP: Pelvic fracture and injury to the lower urinary tract. Surg Clin North Am 68:1057, 1988.)

of contrast material onto the pelvic genitalia or examination table may lead to false-positive findings on the postevacuation radiograph. The postevacuation film may disclose evidence of posterior bladder wall or extraperitoneal extravasation not seen on the anteroposterior radiograph of the filled bladder (Figs. 47-12 and 47-14).

In cases of extraperitoneal bladder perforation, contrast material is evident in the area of the pubic symphysis and pelvic outlet (Fig. 47-15). With intraperitoneal perforation, contrast material outlines intraperitoneal structures (e.g., loops of bowel, the liver, and spleen) (Fig. 47-16).

Several studies have documented that false-negative results are associated with the use of less than 300 to 400 mL, or an age-inappropriate amount, of contrast material for cystography.[17] This has been seen primarily in penetrating bladder injuries in which the perforation from a small-caliber gunshot wound or a thin-blade stab wound can be missed. The anatomically interlacing bladder wall muscle fibers are arranged such that these wounds lend themselves to immediate muscle fiber reapproximation and tenuous sealing of the wound by covering peritoneum and intra-abdominal mesentery. Unless an adequate amount of full-strength contrast material is used to fully distend or even overdistend the bladder, extravasation will not be evident, the injury will be missed, and there will be potential for significant morbidity.

Computed Tomography Retrograde Cystogram. The same anatomic information regarding bladder injury may be obtained with retrograde CT cystography rather than routine plain film radiography.[21-23] CT cystography is best performed in trauma patients who are undergoing CT evaluation for other possible injuries.

www.ketabpezeshki.com 66485457-66963820

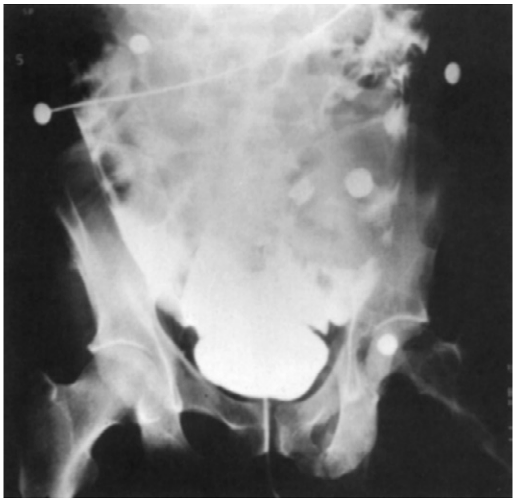

Figure 47-16. Cystographic appearance of intraperitoneal bladder perforation. Cystogram reveals massive intraperitoneal perforation and extravasation. (From Spirnak JP: Pelvic fracture and injury to the lower urinary tract. Surg Clin North Am 68:1057, 1988.)

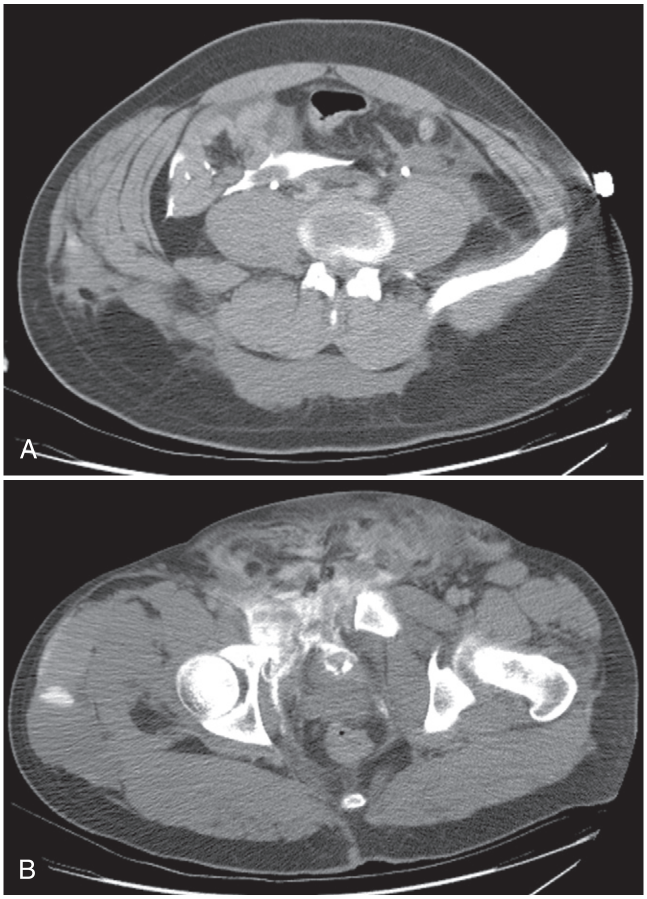

Figure 47-17. Bladder rupture. A, Intraperitoneal rupture shows contrast material extravasated from the bladder outlining loops of bowel in the lower abdomen. B, Extraperitoneal rupture shows contrast material extravasating into the disrupted soft tissue plains of the anterior and left pelvic side wall. (Courtesy Charlotte Radiology, Emergency Radiology Section, Charlotte, North Carolina.)

Following standard CT imaging of the abdomen and pelvis to evaluate for injury, the bladder is filled with water-soluble contrast medium in the same manner as for the retrograde cytogram, and additional CT images are obtained. Postvoid images are not necessary given the additional detail evident on CT imaging. Intraperitoneal rupture is diagnosed on helical CT scan by the presence of extravasated contrast material throughout the abdominal cavity (i.e., contrast ascites). Extraperitoneal extravasation is more difficult to visualize but can be appreciated on images taken through the area of the bladder neck and lower pelvis (Fig. 47-17A and B).

Management

In cases of bladder contusions, there is no evidence of extravasation on retrograde cystography. For these injuries, expectant management with or without Foley catheter drainage is standard practice.[15,24] Most uncomplicated extraperitoneal bladder ruptures heal spontaneously with urinary catheter drainage alone. Indications for operative repair of extraperitoneal ruptures include the presence of concomitant injury to the rectum or vagina, injury involving the bladder neck, or situations in which laparotomy is required for other injuries. Intraperitoneal bladder rupture requires surgical repair. Without operative intervention, lower urinary tract contamination will infect initially sterile urine and promote the development of subsequent bacterial peritonitis. Bladder repairs are never emergencies and normally follow operative repair of life-threatening injuries. Prompt urology consultation is indicated to allow for coordination between surgeons and determination of the optimal timing of the repair.

UPPER TRACT

RENAL TRAUMA

Perspective

Renal trauma rarely occurs in isolation. Concomitant nonurologic injuries may result in hemodynamic instability, necessitating prompt intervention and relegating the search for renal injury to a position of secondary importance. Significant renal injuries define a small subset of the trauma population at large, and mortality from renal trauma accounts for less than 0.1% of trauma deaths.[25] This fact may lead to complacency and causes some of these injuries to be overlooked initially. Renal injuries are graded 1 through 5 according to the American Association for the Surgery of Trauma Organ Injury Scaling Committee guidelines, which identify most injuries requiring operative intervention.[26,27]

Complications

Urinary extravasation is the most common complication of renal trauma, occurring in 10 to 30% of penetrating trauma and 2 to 18% of blunt injuries.[25] There is considerable controversy in the urologic literature regarding the incidence of hypertension after renal trauma, with reported rates varying greatly from as little as 0.2% to as much as 55%.[25,28] Many experts currently believe the overall risk of hypertension after most renal injuries to be quite low.[25,28,29] Factors affecting the risk of hypertension after renal trauma include the specific injury type and severity. Renal artery occlusion, although rare, imparts a risk of hypertension of up to 50%.[25,29]

Anatomy and Physiology

The kidneys are located in the retroperitoneal space, are surrounded by adipose tissue and loose areolar connective tissue, and lie along the lower two thoracic vertebrae and the first four lumbar vertebrae (Fig. 47-18). The kidneys are not fixed. They move with the diaphragm and are supported by their renal arteries, veins, and adipose tissue, which is connected to a layer of fibrous tissue called the *renal fascia* or *Gerota's fascia*.

www.ketabpezeshki.com 66485457-66963820

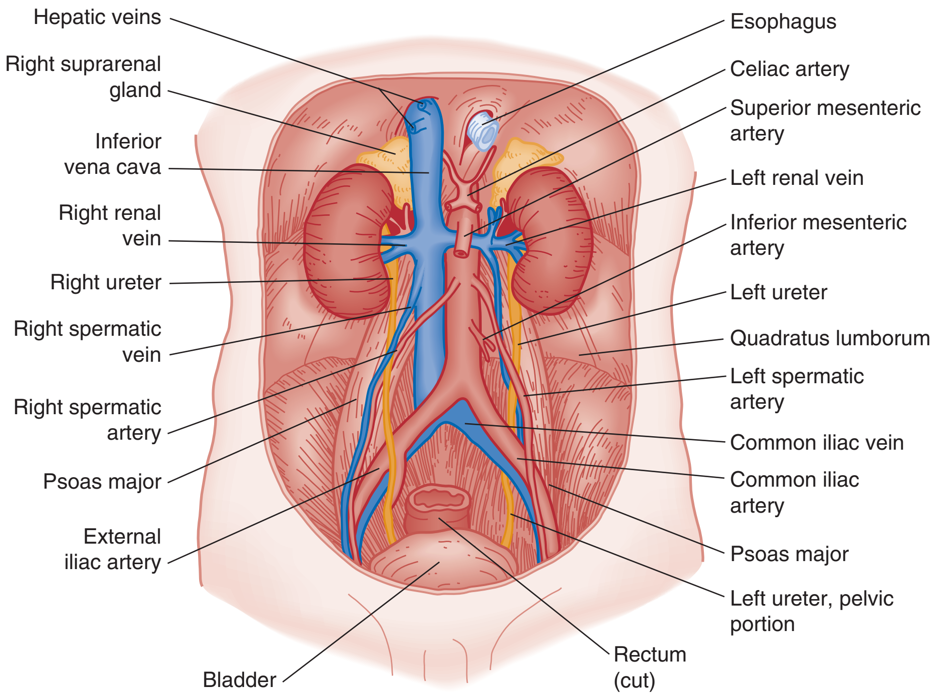

Figure 47-18. Dissection of abdomen showing kidneys and ureters and their relationship to other anatomic features in the retroperitoneal space.

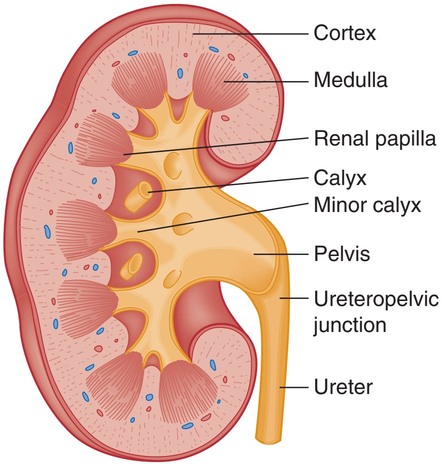

Figure 47-19. Longitudinal section of kidney.

The indented medial border of the kidney is called the *hilum.* The major renal vessels and ureter make up the renal pedicle and enter and exit at the hilum. The longitudinal section of the kidney (Fig. 47-19) shows an outer renal cortex and an inner renal medulla with its columns of Bertin. Each column of Bertin forms a papilla that empties into the renal pelvis. The renal pelvis is a funnel-shaped sac with cup-shaped extensions called *calyces,* which receive urine from each papilla and are the important decompression areas for rises in intrapelvic pressure.

The kidneys are perfused by 1200 mL of blood per minute, or 20 to 25% of cardiac output. Of this, 90% goes to the cortex and 10% to the medulla. Reduced blood flow to the kidney, whether from blunt or penetrating injury, causes renin to be released from the juxtaglomerular cells. Renin enters the bloodstream and combines with a plasma protein to form angiotensin. Angiotensin raises blood pressure by causing arteriolar vasoconstriction and acting on the adrenal cortex to augment aldosterone secretion. Aldosterone acts on the renal tubules to promote sodium reabsorption. Water follows passively with subsequent increase in blood volume. These changes increase blood flow to the kidney and other organs. The body requires only one third of normal renal function to sustain life. It is unusual in cases of genitourinary trauma to lose total renal function unless the patient had only one kidney prior to injury, which carries a 1 in 1000 to 1 in 5000 incidence.[30]

Epidemiology

Renal injury occurs in 1 to 5% of hospitalized trauma patients and represents the most common of all genitourinary injuries.[13,29] Associated organ injuries occur in 61 to 100% of penetrating trauma and 35 to 55% of blunt injuries.[25] Blunt trauma accounts for approximately 90% of injuries and occurs most often after MVCs, falls from heights, or direct blows to the flank. The pathophysiologic mechanisms include rapid deceleration, displacement, and, rarely, an explosion-type injury of the ureteropelvic junction. Penetrating injuries tend to be more severe and are associated with a higher nephrectomy rate.[13]

Renal vein injuries are more common than renal artery avulsions or intimal tears. Both injuries are often associated with rapid deceleration events. Most venous injuries tend to be partial rather than complete tears. As expected, a venous injury can potentially contribute more to a patient's unstable hemodynamic status than an arterial injury, as the protective secondary vasospasm that occurs after arterial transection does not occur with venous injuries. Intravenous contrast-enhanced helical CT identifies most renal artery disruptions, whereas renal vein injuries must be indirectly diagnosed by the presence of a normal-appearing kidney in association with a large hematoma disproportionate to the rest of the radiographic study.

Diagnostic Strategies

Laboratory

Hematuria. The presence, absence, or degree of hematuria correlates poorly with the severity of renal injury. This is especially true in the setting of penetrating trauma. In select cases of blunt

www.ketabpezeshki.com 66485457-66963820

trauma, the distinction between gross and microscopic hematuria can be used to guide clinical decision-making when considered along with the patient's hemodynamic status and the mechanism and severity of injury.[13,29,31,32] Formerly, a trauma patient who exhibited gross or microscopic hematuria was labeled "at risk" for urologic injury and underwent intravenous pyelography. Experience has shown that most of the identifiable injuries were renal contusions that could be managed expectantly. Moreover, in a significant number of severely traumatized patients, vigorous initial fluid resuscitation precluded satisfactory contrast concentration in the kidney, yielding an incomplete, nondiagnostic initial radiographic examination.

In 1989, Mee and associates published the hallmark article that established guidelines for the evaluation and treatment of renal trauma. Their 10-year prospective study of 1146 consecutive patients with blunt (88%) and penetrating renal trauma established that clinically significant blunt renal injuries are associated with gross hematuria, microscopic hematuria with shock (any systolic blood pressure less than 90 mm Hg), or, rarely but importantly, a history of sudden deceleration injury without hematuria or shock. In the same series, there was no correlation between the presence or absence of hematuria and the extent of renal injury among 139 cases of penetrating trauma.[32]

Pediatrics. In children the kidney is the most commonly injured genitourinary organ.[33] Controversy exists in the urologic literature as to whether the adult criteria for renal imaging after blunt trauma can be safely applied to the pediatric population.[29,34,35] Owing to significant differences in physiology, hypotension is a late and unreliable indicator of shock in children.[13,29] In addition, unlike in adults, major blunt renal injuries can occur in the presence of microhematuria. The literature has defined 50 RBCs per high-power field (hpf) as the threshold below which imaging could be confidently deferred without missing significant injuries in children.[35,36] Current guidelines support imaging for pediatric (16 years or younger) patients with blunt renal trauma in the presence of gross hematuria, with microhematuria greater than 50 RBCs/hpf, or with significant deceleration injuries.[29,37] As with adults, intravenous contrast-enhanced helical CT scanning is the diagnostic imaging technique of choice.

Radiology

Computed Tomography. Intravenous contrast-enhanced helical CT is the diagnostic radiographic procedure of choice in evaluating significant upper tract renal trauma.[13,29,31,38] CT detects renal contusions, lacerations, renal pedicle injuries, devitalized segments, and urinary extravasation (Fig. 47-20). It allows for grading of renal injuries and provides important information about concomitant nonurologic injuries to abdominal and pelvic structures. Additional images obtained 10 minutes after contrast injection enable the detection of delayed extravasation and increase diagnostic accuracy.

Angiography. Angiography may be a useful adjunct to CT imaging in the stable trauma patient with suggested renovascular injury, such as renal artery thrombosis, laceration, or pseudoaneurysm, and may be therapeutic in cases in which stenting or embolization is indicated.[21,31,38]

Intravenous Pyelography. Formerly, intravenous pyelography was the most common imaging modality used in the evaluation of renal trauma. It has been shown to be less accurate than CT, is time-consuming and labor-intensive, and images only the urinary tract.[31] Despite these significant limitations, it may play a limited role in the initial evaluation of suspected renal trauma when CT is not readily available. In patients requiring immediate surgical intervention for other indications, a "one-shot intravenous pyelogram" (IVP) obtained in the emergency department or, more commonly, on the operating table may provide limited information to help the surgeon stage upper tract injuries and confirm bilateral renal function. This test is performed by obtaining a single KUB film 10 minutes after the injection of 2 mL of intravenous contrast per kilogram (maximum 150 mL).[30]

Ultrasound. Ultrasound is not sufficiently sensitive to rule out possible renal trauma, as it has been shown to miss up to 78% of known renal injuries.[31,38] In the multiply injured trauma patient, ultrasound is useful in the evaluation for free fluid in the abdomen and pelvis, which may herald other significant nonrenal injuries; however, this modality cannot reliably distinguish blood from other types of fluid such as ascites or extravasated urine.[39] Moreover, free intraperitoneal fluid may be absent in up to 65% of isolated renal injuries.[21,38]

Management

Blunt Injury

In the absence of a significant deceleration mechanism, adult blunt trauma patients without gross hematuria or shock (any systolic blood pressure <90 mm Hg) and pediatric blunt trauma patients with microhematuria of 50 RBCs or fewer per high-power field can be confidently discharged from the emergency department if hospital admission is not otherwise indicated. Outpatient urology follow-up until microhematuria has cleared is advisable to be certain it does not represent another more serious underlying condition.

The optimal management of blunt renal trauma depends on the type and severity of injury (Figs. 47-21 and 47-22), the patient's hemodynamic status, and the management plan for any associated nonurologic injuries. The American Association for the Surgery of Trauma organ injury severity scale for the kidney stratifies injuries and has been shown to correlate with the need for surgical intervention and the rate of nephrectomy.[26] Grade I injuries include simple contusions and subcapsular, nonexpanding hematomas without parenchymal laceration. Grade II injuries are parenchymal lacerations less than 1 cm in depth without urinary extravasation and a stable, nonexpanding hematoma. Grade III injuries are parenchymal lacerations greater than 1 cm in depth without urinary extravasation. Grade IV injuries involve lacerations extending through the cortex, medulla, and collecting system or main renal artery or vein injuries with contained hemorrhage. Grade V injuries involve completely shattered kidneys or avulsion of the renal hilum and devascularization of the kidney.[26] In one large retrospective review of 2467 patients with renal injury, the need for surgery increased from 0% of grade I injuries to 93% of grade V injuries. Likewise, the nephrectomy rate increased from 0% of grade I and II injuries to 86% of grade V injuries. Given that 80 to 90% are grade I or II, most blunt renal injuries can be managed nonoperatively with bed rest until any gross hematuria clears and with periodic follow-up imaging to assess for injury resolution and to document renal function.

Immediate operative intervention is indicated for persistent life-threatening hemorrhage of possible renal origin. Restoration of normal renal function is unlikely after main renal artery injury, and nephrectomy may be required, especially in the presence of longer than 2 to 3 hours of complete or 6 hours of partial renal ischemia.[29,40] In select patients, arteriography with hemorrhage control by embolization is a reasonable alternative to laparotomy.[13] Of note, arterial embolization results in infarction of the affected renal segment, imparting a risk of infection and posttraumatic hypertension. These risks can be minimized by superselective catheterization and embolization of peripheral branches of the renal artery when possible, based in the specific injury and expertise of the interventionalist. When laparotomy is required

for other injuries before adequate radiographic evaluation, blunt renal trauma may be surgically staged. In this setting, renal exploration is indicated in the presence of an expanding, pulsatile, or uncontained retroperitoneal hematoma that is thought to indicate renal pedicle avulsion or when the injured kidney is not visualized on the one-shot IVP.[31]

Penetrating Injury

In cases of penetrating renal trauma, the presence or absence of hematuria is of no consequence in predicting upper urinary tract injury. The location of the penetrating injury in relation to the urinary tract is the most important determining factor in deciding

www.ketabpezeshki.com 66485457-66963820

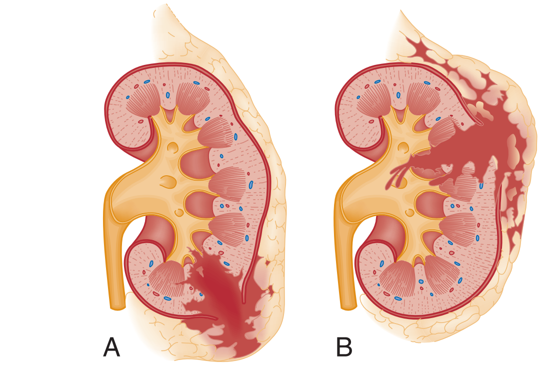

Figure 47-21. Major renal lacerations. **A,** Deep medullary laceration. **B,** Laceration into collecting system. (From Nicolaisen GS, et al: Renal trauma: Re-evaluation of the indications for radiographic assessment. J Urol 133:183, 1985.)

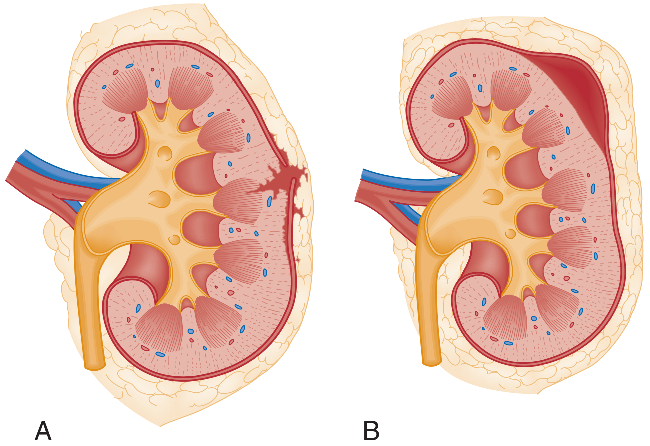

Figure 47-22. Minor renal injuries. **A,** Minor renal laceration. **B,** Renal contusion. (From Nicolaisen GS, et al: Renal trauma: Re-evaluation of the indications for radiographic assessment. J Urol 133:183, 1985.)

the need for radiographic investigation. Therefore the absence of hematuria in a patient with a gunshot or stab wound in proximity to the urinary tract does not eliminate the need for intravenous contrast-enhanced CT as the initial diagnostic examination. Significant injuries to the kidney and ureter may occur in penetrating trauma *without* hematuria.[13,29,32] Additional images obtained at 10 minutes after contrast injection are indicated to evaluate for delayed contrast extravasation and maximize the sensitivity of the study. The majority of penetrating renal injuries require surgical intervention.

URETERAL TRAUMA

Pathophysiology

Approximately 80% of ureteral injuries are iatrogenic, resulting from complications of abdominal or pelvic surgery, with the remainder caused by external trauma. The ureters are relatively protected from injury by the bony pelvis, vertebral column, and psoas muscle. Thus ureteral trauma is rare, present in approximately 3 per 10,000 trauma admissions.[41] Gunshot wounds are the most frequently reported mechanism, with ureteral injuries complicating 2 to 3% of abdominal gunshot wounds.[42,43]

Blunt force trauma causes ureteral injury when a significant decelerating force results in avulsion of the ureter from its fixed points at the ureteropelvic junction or, less commonly, the ureterovesicular junction. Owing to the significant force required for ureteral injury, concomitant major organ injury occurs in approximately 90% of cases, and hypotension is present in more than 50%.[44]

Clinical Features

There are no reliable signs and symptoms of ureteral injury in the acutely injured patient. Hematuria (gross or microscopic) is frequently present but may be absent in more than 25% of patients, and thus its absence alone cannot be relied on to exclude the diagnosis.[44] After blunt trauma, ureteral injury should be considered in patients with a significant decelerating mechanism, gross hematuria, or microscopic hematuria with hypotension. With penetrating mechanisms, ureteral injury should be considered when the injuring force occurs in proximity to the anatomic course of the ureter. Missed ureteral injury may manifest in a delayed fashion with a variety of signs and symptoms, including fever, nausea and vomiting, hematuria, flank pain, and a palpable flank mass.

Diagnostic Strategies

Intravenous contrast-enhanced CT of the abdomen and pelvis is highly sensitive for visualization of upper tract injuries and is often indicated for the investigation of associated nonurologic injuries. Additional images obtained 10 minutes after contrast injection enable the detection of delayed extravasation and increase diagnostic accuracy.[21]

Retrograde pyelography (Fig. 47-23) is slightly more sensitive than intravenous contrast-enhanced CT for the evaluation of ureteral injury, but its performance is frequently impractical in the multiply injured patient and it is rarely undertaken in lieu of CT. Likewise, a formal IVP, although sensitive, is of limited usefulness owing to the significant time required for study completion.[44] In patients requiring immediate surgical intervention for other indications, a one-shot IVP performed in the emergency department or, more commonly, on the operating table may provide limited information to help the surgeon stage upper tract injuries and confirm bilateral renal function. This test is performed by obtaining a single KUB film 10 minutes after the injection of 2 mL/kg of intravenous contrast (maximum 150 mL). The presence or absence of ureteral injury is subsequently confirmed during operative exploration.

Management

Operative repair is indicated for all ureteral injuries. With early diagnosis and appropriate treatment, the kidney and ureter can be saved in most cases. The complications of missed ureteral injuries are significant and include extended hospital stays, persistent urinoma, sepsis, loss of renal function, and death.[45,46]

EXTERNAL GENITALIA

PENILE TRAUMA

Anatomy

The penis contains three masses of erectile tissue (Fig. 47-24). The two corpora cavernosa constitute the main bulk and lie in the center of the penis. The smaller corpus spongiosum lies on the ventral surface of the penis, encases the urethra, and expands at the penile tip to form the glans penis. Blood is supplied by arteries lying in each of the three erectile masses and by the two dorsal penile arteries. A single dorsal vein drains most of the penis. The tunica albuginea is a dense fibrous envelope that surrounds the corpus spongiosum and each corpus cavernosum. Buck's fascia

www.ketabpezeshki.com 66485457-66963820

overlies the tunica albuginea, enclosing all three of the erectile masses, the dorsal arteries, dorsal nerve, and deep dorsal vein within a common compartment.

Clinical Features

Important historical factors to ascertain include the mechanism of injury and the state of the penis, flaccid or erect, at the time the injuring force was inflicted, as well as tetanus immunization status. Penile injuries range from small lacerations or contusions to skin degloving or amputation. Strangulation injuries of the penile shaft inflicted by an encircling piece of string or hair may be seen in children (Fig. 47-25). Adolescents and adults may have various objects of penile incarceration such as bottles, washers, and metal rings (Fig. 47-26). These objects are often used to facilitate masturbation, prevent detumescence, and heighten sexual pleasure. Prolonged application of these devices may result in loss of superficial skin, deep urethral necrosis, or eventual need for penile amputation.[47]

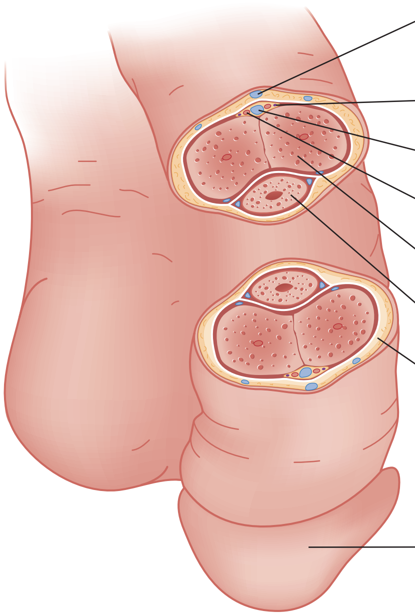

Figure 47-24. Cross-sectional view of the penis.

The pendulous nature of the flaccid penis provides a measure of protection from blunt injury. By contrast, forceful bending of the erect penis may result in traumatic rupture of the corpus cavernosum, or penile fracture, owing to tearing of the tunica albuginea. This injury may occur during vigorous sexual intercourse or masturbation.[48] The patient often reports hearing a snapping sound followed by immediate pain, detumescence, and a slowly progressive penile hematoma (Fig. 47-27). In the majority of cases, the swelling and ecchymosis are localized to the penile shaft and contained by Buck's fascia. The resultant appearance has been described as an "eggplant deformity." If Buck's fascia is torn, blood may track along fascial planes to the scrotum, perineum, and pubis. The corporal defect may be palpable on physical examination. Urethral injury occurs in 10 to 38% of penile fractures.[47] The diagnosis is suggested by the presence of gross hematuria, blood at the urethral meatus, or the inability to void, but may be possible even in the absence of these clinical findings. Urethral injury is present in up to 50% of all penetrating penile injuries.[21]

Penetrating trauma to the external genitalia may be inflicted by stab wounds or gunshot wounds. These injuries are frequently associated with concomitant injuries to the bladder, urethra, rectum, testis, and iliac and femoral vasculature.[47] Penile amputation may result from interpersonal violence or be self-induced as a result of severe psychiatric disease.

The testicles are vulnerable to injury because of their location but are relatively protected by the mobility of the scrotum, the tough tunica albuginea that surrounds the testes, and the cremasteric reflex. Eighty-five percent of testicular injuries are inflicted by blunt trauma, most commonly during sporting endeavors.[49] Mechanisms include falls, kicks, and direct strikes by thrown

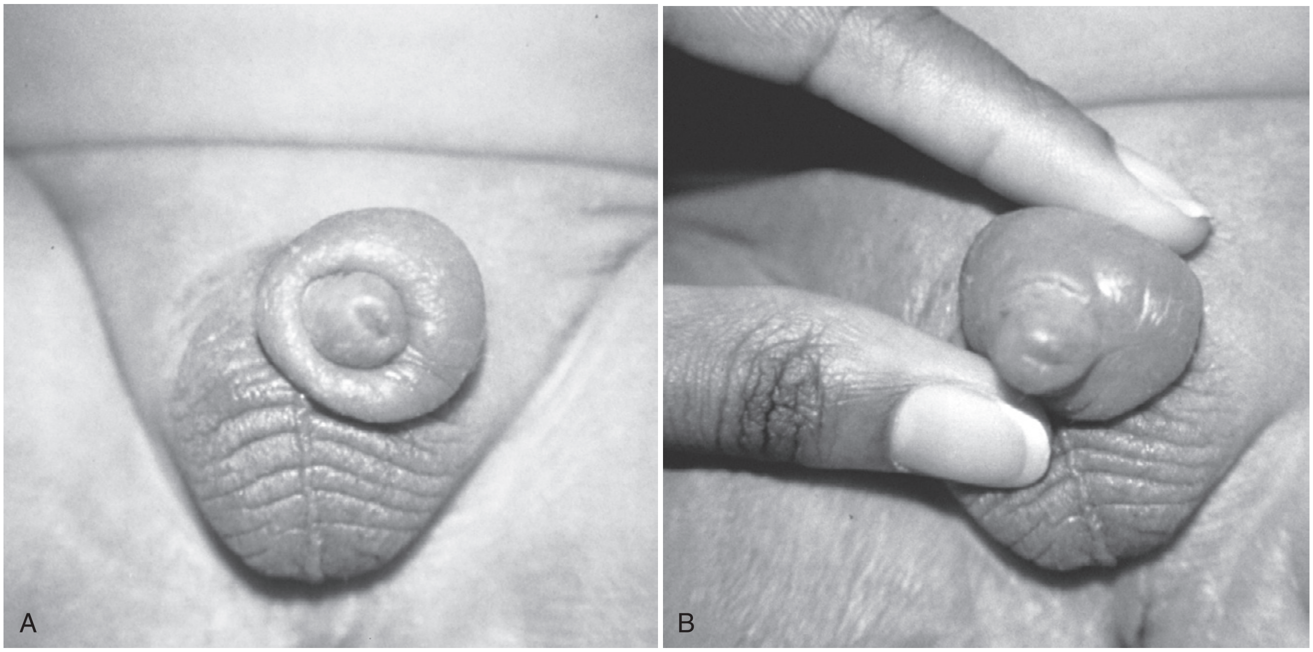

Figure 47-25. Idiopathic foreskin edema. **A,** This is the same picture that can be seen with penile strangulation injuries in children. **B,** The edematous foreskin is retracted proximally and distally, and encircling hair, string, or other objects that may lead to vascular compromise are sought.

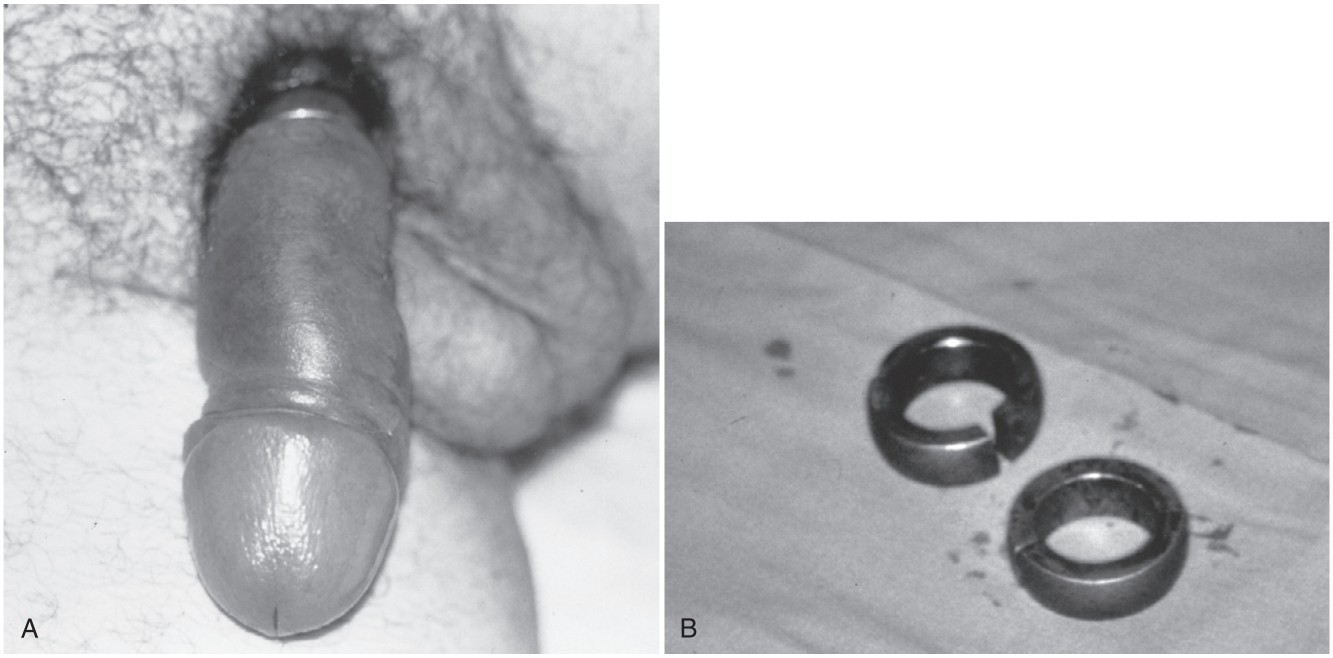

Figure 47-26. A, Self-induced priapism. This patient placed two steel washers (B) around the base of his penis to prolong his erection. Subsequent priapism developed, and the incarceration necessitated emergency intraoperative removal with a pneumatic orthopedic drill.

Figure 47-27. Fracture of the penis. Traumatic rupture of the corpus cavernosum, usually associated with sexual activity, results in a profound penile hematoma, most often requiring operative repair.

objects. Testicular rupture occurs in more than 40% of blunt scrotal trauma in patients who come to the hospital.[13,50] Additional injuries include scrotal hematoma, hematocele, intratesticular hematoma, traumatic testicular torsion, testicular avulsion, testicular displacement, and epididymal injury. Symptoms include severe pain, faintness, nausea, vomiting, and occasionally urinary retention secondary to pain. Physical examination is often inadequate owing to significant pain and swelling.[50]

Genital bite wounds may be inflicted by humans during sexual activity or by animals. The predominant human oral bacterial organism in genital bite wounds is *Eikenella corrodens;* however, transmission of viral infections, including hepatitis and human immunodeficiency virus (HIV), is possible.[47] Dog and cat bites may lead to pathogenic infections with *Pasteurella multocida* and anaerobic organisms. With certain animal bites, the possibility of rabies transmission is considered.

Injuries to the female external genitalia may result from pelvic fractures, sexual assault, or straddle-type mechanisms. Hematomas and lacerations are the most common injuries. Physical examination includes evaluation for associated injuries of the vagina, urethra, bladder, and rectum. Screening for interpersonal violence should be considered in all women with injuries to the external genitalia.

In children, blunt or penetrating injury to the external genitalia may be inflicted by straddle-type injuries or falls onto sharp objects. Child abuse should be considered and investigated when the explanation given for the event does not match the type of injury and objective physical findings. Examples include bruises that look like pinches, cigarette burns, or a penile injury reportedly caused by a falling toilet seat in a child who is too small to stand unsupported.

Diagnostic Strategies

A careful physical examination is usually sufficient to diagnose most blunt penile injuries. Retrograde urethrography is indicated in cases of suggested urethral injury, which should be considered in the presence of concomitant penile or scrotal hematoma, gross hematuria, or blood at the urethral meatus. Rarely, atypical presentations of penile fracture may require adjunctive imaging. Corpus cavernosography, ultrasound, and magnetic resonance imaging have all been advocated for this indication.[47,51,52] The acquisition of penile imaging should occur in consultation with the treating urologist.

Unlike with penile injuries, physical examination is frequently inadequate for the assessment of blunt scrotal trauma. Ultrasound is the test of choice owing to its higher than 95% sensitivity for testicular rupture when the diagnosis is based on the finding of a heterogeneous echo pattern of the testicular parenchyma with a loss of contour definition (Fig. 47-28).[50,53] Scrotal imaging is rarely indicated after penetrating trauma because surgical exploration is usually warranted.

www.ketabpezeshki.com 66485457-66963820

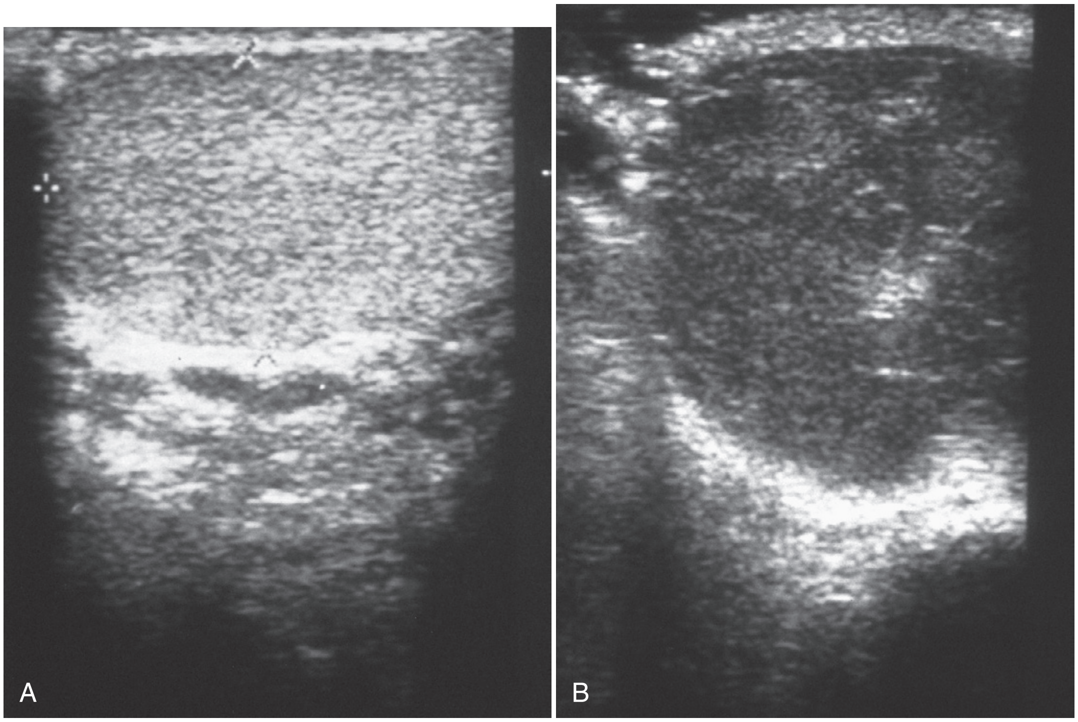

Figure 47-28. Testicular rupture. **A,** Testicular ultrasonogram demonstrates the normal homogeneous testicular pattern. **B,** The heterogeneous pattern of injury, tumor, or disruption.

Management

Constricting devices are promptly identified and removed, a procedure that can test the ingenuity of even the most experienced emergency physician (see Fig. 47-26). Various creative techniques with saws, metal cutters, or emery wheels may be necessary to remove some metal objects. Reconstructive surgery of the penis may eventually be needed but is usually delayed until penile tissue viability has been determined. Fortunately, each corpora body has a separate blood supply and may be preserved even though the penile skin may slough, necessitating skin grafting.

Superficial penile hematomas without rupture of the tunica albuginea and with no immediate detumescence of the erect penis may be treated conservatively with the local application of ice and administration of nonsteroidal anti-inflammatory drugs (NSAIDs).[13] Superficial lacerations of the penile and scrotal skin may be primarily approximated with 4-0 chromic or Vicryl absorbable suture. Patients with degloving penile injuries and scrotal skin loss should be treated by a urologist and plastic surgeon in the operating room with irrigation, débridement, and skin flaps or skin grafts.

With penile fracture, early surgical repair of the tunica albuginea defect (within 24-36 hours after injury) is indicated to maximize functional outcomes.[13,49,51] Early surgical exploration and repair are recommended for most penetrating injuries to the penis.[54] Penile amputation may be managed by reimplantation or local reshaping. Successful reimplantation may be achieved even up to 24 hours after amputation.[47,49] The recovered amputated penis should be carefully wrapped in sterile, saline-moistened gauze and placed in a plastic bag. That bag is then placed in a second plastic bag containing ice. Hemostasis of a bleeding penile stump can usually be achieved with direct pressure.

After blunt scrotal trauma, surgical exploration is indicated for treatment of testicular rupture, large hematocele, traumatic torsion, and testicular dislocation. Testicular salvage rates are 80 to 90% when surgical exploration occurs within 72 hours and less than 50% when exploration is delayed beyond 72 hours.[49] In patients with a sonographically normal, homogenous-appearing testicle, exploration is not necessary.[50] Testicular contusions are treated with bed rest, ice packs, NSAIDs, and urologic follow-up. Surgical exploration is indicated in nearly all cases of penetrating scrotal trauma.[50,54]

Patients with simple bite wounds within 6 to 12 hours after injury without gross contamination can be treated with irrigation and primary closure.[47,49] Broad-spectrum antibiotic coverage with an agent such as amoxicillin-clavulanate is indicated. Grossly contaminated or infected wounds should be irrigated, covered with a sterile dressing, and managed in conjunction with the consulting urologist.

Human bite wounds can cause a potentially serious polymicrobial infection. When cellulitis is present, immunocompromised patients should be admitted to the hospital for broad-spectrum intravenous antibiotic coverage for both aerobic and anaerobic organisms with an agent such as piperacillin-tazobactam. Immunocompetent hosts may be treated in the outpatient setting with broad-spectrum oral antibiotics, NSAIDs, and reevaluation in 48 hours.

www.ketabpezeshki.com 66485457-66963820

KEY CONCEPTS

- Diagnostic evaluation of the urinary tract is generally undertaken in retrograde fashion, that is, suggestion and elimination of urethral injury before bladder injury before ureteral or renal injury.
- Urethral injury is suggested by the presence of a pelvic fracture, blood at the urethral meatus, or evidence of a perineal, scrotal, or penile hematoma.
- Gross hematuria alone or in conjunction with a pelvic fracture is the absolute marker for significant bladder injury. Grossly clear urine in a trauma patient without a pelvic fracture virtually eliminates the possibility of bladder rupture.
- Bladder injury should be ruled out by retrograde cystography, which is more accurate than methods that use anterograde contrast administration.
- Adults at risk for significant blunt renal injury have gross hematuria, microhematuria with shock, or a history of sudden deceleration. Children at risk for significant blunt renal injury have hematuria with more than 50 RBCs/hpf or a history of significant deceleration.
- Intravenous contrast-enhanced helical CT with delayed images at 10 minutes after contrast injection is the imaging modality of choice for suggested upper tract injury.

CHAPTER 48

Peripheral Vascular Injury

Edward J. Newton and Sanjay Arora

PERSPECTIVE

Injury to the major peripheral arteries or veins is often life-threatening but invariably poses a threat to the viability of the affected limb. Historically, because of rapid blood loss, injury to major vessels was often quickly fatal in the field. Most patients who survived to reach a hospital had relatively minor vascular injuries. However, with the advent of modern emergency medical services systems with advanced extrication methods and rapid transport, more patients with major vascular injury reach the hospital alive.[1] In addition, the incidence of penetrating civilian injuries from interpersonal violence and blunt injuries from motor vehicle–related trauma in the United States has increased dramatically during the past 50 years. Consequently, emergency physicians are frequently confronted with critically ill patients harboring overt or occult vascular injuries. Management of vascular injuries has evolved with advances in diagnostic methods and surgical techniques. Treatment of vascular injuries before and during World War II was simple ligation of the peripheral artery or vein involved. This approach resulted in limb amputation rates ranging from 40% for axillary artery injuries to 72% for popliteal artery injuries. During the Korean War, routine attempts to repair injured arteries decreased the amputation rate for popliteal injuries to 32%.[2,3] During the Vietnam War, repair of penetrating axillary and popliteal artery injuries with routine angiography and improved surgical techniques resulted in decreases in the amputation rate to as low as 5 and 15%, respectively, which approach the current rates of amputation for civilian injuries.[2,3] Owing to the nature of the munitions and the extensive use of body armor in the Iraq and Afghanistan wars, the proportion of severe wounds of the extremities has increased. The amputation rates thus far are 5% for upper extremity and 21% for lower extremity vascular injuries.[2] However, extrapolation of high-velocity military wound data to low-velocity civilian gunshot wounds may not be valid, and even lower rates might be expected with civilian wounds.

Tremendous progress has been achieved in diagnostic and therapeutic techniques for dealing with peripheral vascular injuries, and several noninvasive diagnostic modalities have emerged as accurate alternatives to surgical exploration or angiography. These techniques are easily used in the emergency department, and the goal of timely detection and repair of serious vascular injuries is achievable in the vast majority of cases.

Epidemiology

Throughout the world, the causes of peripheral vascular injuries are divided almost equally between blunt and penetrating mechanisms. In the United States, 56 to 90% of these injuries are a result of penetrating wounds, mainly because of the high rate of penetrating trauma in inner-city urban areas.[4-7] Although the incidence of low-velocity gunshot wounds has decreased during the past decade, gunshot wounds remain the second leading cause of death in the 15- to 34-year-old age group in the United States.[8] Major venous injuries are present in 13 to 51% of all cases, but more than 80% of these are associated with arterial injury as well.[9] Approximately 90% of patients with vascular injury are male, and most are younger than age 40 years.[5] Because of the increased use of percutaneous endovascular diagnostic and therapeutic procedures, the incidence of iatrogenic vascular injuries has increased and accounts for up to one third of all cases in some series.[10,11]

PRINCIPLES OF DISEASE

Pathophysiology

Blunt and penetrating types of trauma result in a similar spectrum of vascular injuries, although the mechanisms of injury differ. Although blunt vascular injuries are less common than penetrating injuries, they are often more severe and more commonly result in amputation because of associated injuries to nerves, bone, and soft tissue. Certain mechanisms of injury, such as animal bites that crush and lacerate vessels, combine penetrating and blunt mechanisms.

Penetrating Trauma

Penetrating trauma from gunshot wounds results in the formation of a temporary cavity within distensible soft tissues with almost immediate recoil of these tissues. The size of the cavity and hence the degree of soft tissue injury depend principally on the velocity of the missile, as well as the tumble and yaw of the bullet. Consequently, gunshot wounds can cause direct arterial laceration or transection in addition to concussive injury at some distance from the track of the bullet. The latter injuries tend to be tears in the intima of an artery with subsequent thrombosis that may not become apparent for hours to months after the injury. Ricochet of bullets that are deflected by bone make predicting the trajectory less accurate that with stab wounds.

Stab wounds can cause vascular injury by complete or partial transection of vessels. Partial laceration of an artery may produce few symptoms of arterial insufficiency on initial evaluation but commonly results in delayed complications. The vascular structures at risk can be predicted more reliably with stab wounds than with gunshot wounds by taking into consideration the anatomic location, the depth and direction of the wound, and the implement involved.

Shotgun wounds are less common than gunshot or stab wounds and cause injuries varying from minor soft tissue wounds to

www.ketabpezeshki.com 66485457-66963820

massive destruction of soft tissue and bone, depending primarily on the range from which the shotgun was fired. The presence of multiple missiles ranging from 9 or 10 (buckshot) to dozens (birdshot) also complicates the evaluation of these injuries because of the many potential sites for vascular injury to occur. In addition, close-range shotgun wounds (<3 yards) can cause significant blunt trauma to blood vessels as well as a higher rate of bone and nerve injury than occurs with gunshot wounds. Migration of pellets or bullets proximally through the venous system to the heart or migration through an artery with subsequent distal occlusion has been reported frequently as a delayed complication.

Blunt Trauma

Blunt injury involves avulsion forces that can stretch vessels beyond their capacity or direct crushing injury that disrupts the vessel wall. Fracture fragments resulting from blunt extremity trauma can lacerate or entrap vessels. Vascular injury can range from small intimal tears to complete avulsion of arteries and nerves. Open avulsion injury of a limb is particularly severe because the skin is the final structure to tear, and once such tearing has occurred, it is inevitable that vessels and nerves will be torn as well. Vascular injury also should be suspected in patients with massive soft tissue avulsion or crush injury, displaced long bone fractures, electrical or lightning injuries, and severe burns, as well as in those with compartment syndrome from trauma or prolonged immobilization as a result of stroke, coma, drug overdose, or other causes.[12-15] Bites that are inflicted by large animals, such as dogs used by law enforcement, are particularly prone to arterial injury and wound complications.[12,13] Collateral circulation may continue to perfuse the limb adequately, but injuries that occur proximal to the collateral branch point or that involve both the main trunk and collateral branches will preclude adequate flow.

Distal ischemia results from the inability of tissues to continue aerobic metabolism. Eventually, anaerobic metabolism consumes all substrate, thereby resulting in the accumulation of lactic acid. As ischemia progresses, cellular integrity is lost and irreversible cell death occurs. A vicious cycle of tissue edema and further impairment of the blood supply occurs.

When no specific measures are taken to cool the limb, it is said that the limb is undergoing “warm ischemia” at room temperature. Although the time in individuals may vary, 6 hours of complete warm ischemia is generally considered the point at which irreversible nerve and muscle damage begins to occur. After 6 hours of warm ischemia, 10% of patients will have irreversible damage; by 12 hours, 90% will have irreversible damage. Artificially cooling the limb to just higher than freezing temperature (cold ischemia) will reduce the metabolic demands of unperfused tissues and greatly prolong the tissue’s tolerance of ischemia to 24 hours or more. Animal studies suggest that hyperbaric therapy may be useful in repaired limbs that have undergone prolonged warm ischemia.[16]

Two main types of vascular injury can result from trauma: *occlusive injury* (transection, thrombosis, and reversible spasm), in which all effective perfusion distal to the occlusion is lost, and *nonocclusive injury* (intimal flap, dissection, arteriovenous fistula [AVF], and pseudoaneurysm), in which some arterial flow continues past the injury.

Complete Occlusive Injury

Transection. The most common vascular injury is complete transection in which distal flow is effectively eliminated. Cleanly transected arteries will often retract and undergo spasm so that blood loss is minimized. With longitudinal arterial lacerations and venous injuries, blood loss cannot be limited by this means, and such injuries tend to result in greater blood loss. Pulsatile bleeding may lead to exsanguinating hemorrhage and shock.

Figure 48-1. Complete thrombosis of the distal brachial artery after reduction of a posterior elbow dislocation. (Courtesy D. Demetreades, MD.)

Thrombosis. Intraluminal thrombosis (Fig. 48-1) may occur in an injured artery acutely (within 24 hours) or may be delayed for many months. Acute thrombosis is initiated by stasis resulting from compression of the artery or from a disruption in the intima of an artery that becomes a nidus for thrombus formation. As the thrombus propagates, complete occlusion of the vessel can occur. Delayed thrombosis can occur months to years after injury if the injured vessel heals with stricture formation and decreased blood flow distally, followed by stasis and clot formation.

Reversible Arterial Spasm. The precise cause and incidence of significant reversible arterial spasm after trauma are unknown. In the case of arterial transection, arterial spasm is beneficial and limits hemorrhage. In other cases, however, the segmental arterial spasm occurs at some distance from the site of traumatic injury and can produce severe distal ischemia. Arterial spasm is particularly common in children. The spasm usually reverses with conservative treatment (topical warm saline or topical nitroglycerin paste), but prolonged spasm may require infusion of vasodilators such as nitroglycerin, calcium channel blockers, alpha-blockers, nitroprusside, specific prostaglandin inhibitors, or warm saline.[17] In many series, segmental arterial spasm is the most common arteriographic finding. However, it should never be assumed on clinical grounds that symptoms of ischemia are a result of arterial spasm; that diagnosis is based on arteriographic results only.

Nonocclusive Injuries

Intimal Flap. An intimal flap occurs when there is a break in the intima of a vessel, generally from excessive stretch or concussive forces. Although flow is not altered by small flaps and the associated soft tissue wounds often appear benign initially, these intimal flaps may become a nidus for thrombosis that can occur hours to months after the initial injury. However, most intimal flaps heal spontaneously, and asymptomatic injuries that do not disrupt perfusion of the limb can be treated conservatively with antiplatelet agents such as clopidogrel.

www.ketabpezeshki.com 66485457-66963820

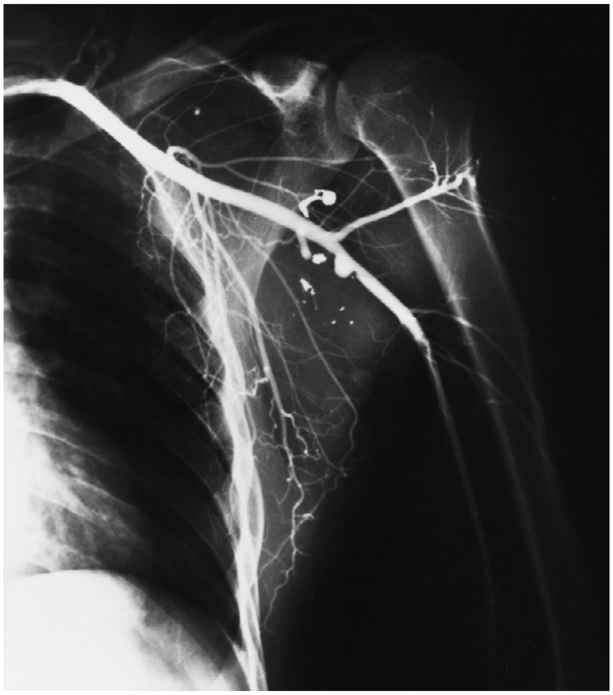

Figure 48-2. Multiple small pseudoaneurysms of the axillary artery after penetrating injury. (Courtesy D. Demetreades, MD.)

Pseudoaneurysm. A true aneurysm contains all three layers of the vessel wall (intima, media, and adventitia) and rarely is caused by trauma. A pseudoaneurysm is formed following a tear in a vessel wherein the hemorrhage is contained by surrounding fascia and the resulting hematoma is gradually encased by a capsule of fibrous tissue, analogous in consistency to the adventitia of a normal vessel (Fig. 48-2). Because it is relatively thin walled, rupture of a pseudoaneurysm is a distinct possibility. In addition, because its diameter inevitably expands under arterial pressure over days to months, compression of adjacent tissue may result in neuropathy, venous obstruction with resultant peripheral edema and venous thrombosis, and even erosion into adjacent bone.[18] The cavity of a pseudoaneurysm is in direct communication with the lumen of the vessel, so embolization of mural clots may produce distal arterial occlusion. Patients with pseudoaneurysm are commonly seen months to years later with symptoms of compression neuropathy or peripheral arterial embolism or for investigation of a soft tissue "tumor" that represents the growing aneurysm.

Arteriovenous Fistula. An AVF is formed when both the artery and an adjacent vein are injured. Higher-pressure arterial flow is directed into the lower-pressure vein, thereby diverting the blood supply to distal tissues and engorging the distal veins. Because the aperture of the fistula is often relatively narrow and thus results in turbulent flow, a bruit and palpable thrill are common diagnostic findings. Symptoms are primarily those of distal ischemia, but rarely, high-output congestive heart failure may occur when large central vessels are involved. Symptoms are often delayed for months because it takes time for the fistula to mature.

Compartment Syndrome. Compartment syndrome is most common after crush injury or a long bone fracture but may also be seen after reperfusion of an ischemic limb. Initially, blood flow is diminished and the injury can be considered nonocclusive. Progressive edema elevates tissue pressure above capillary pressure, thus ending arterial perfusion and initiating a cascade of events that results in compartment syndrome. The risk for this complication is increased when ischemia time is prolonged; in the presence of combined arterial and venous injury; after ligation or repair of a major artery or vein; or in the presence of significant soft tissue injury, frequently concomitant with a long bone fracture.[5] Smaller caliber vessels are compressed first, whereas larger vessels remain relatively patent and compartment pressure rarely exceeds arterial pressure, so pulses may be palpable until very late in the course. If the condition is allowed to progress, however, all blood flow may end and the injury is then an occlusive one. After restoration of arterial flow to a previously ischemic limb, a cascade of reperfusion injury has been identified that results from release of oxygen free radicals, lipid peroxidation, and influx of intracellular calcium. These mediators give rise to progressive cellular damage, edema, and necrosis, thereby propagating the vicious cycle that increases compartment pressure.[19] Consequently, frequent reexamination of the limb is indicated to assess compartment pressure after arterial repair or in the high-risk circumstances listed earlier.

CLINICAL FEATURES

Detection and treatment of vascular injuries takes place within the context of the overall resuscitation of the patient according to established principles of trauma care.[20] If the source of bleeding is readily identifiable, it is compressed with digital pressure. While control of active bleeding is being achieved in this manner, detection and treatment of other life-threatening injuries proceed concurrently. Peripheral vascular injury can occur coincident with other life-threatening trauma, which may take higher priority in resuscitating the patient. In other cases, peripheral vascular injury may be the most serious or only injury, and evaluation and management of this type of injury can proceed directly. Despite rapid transport to a hospital through a modern emergency medical service, injury to large central arteries and veins is still often fatal, and many of these deaths occur before medical contact. Patients who survive to reach the hospital may have obvious exsanguinating hemorrhage or only very subtle signs of vascular injury. Many patients have no evidence of injury but are considered at risk for vascular injury because of penetrating wounds that traverse the course of major neurovascular bundles or because they have sustained high-risk injuries such as posterior knee dislocation. Patients who remain hypotensive after an initial fluid challenge may harbor an occult vascular injury if no other cause is found. In addition, patients with symptoms of intermittent claudication or with unexplained peripheral embolization and a history of previous trauma to the limb should be suspected of having occult arterial injury.

Peripheral vascular injury can be divided into three categories by physical examination: hard findings, soft findings, and asymptomatic high-risk wounds based on the mechanism of injury.

Hard Findings of Vascular Injury

Many patients have the classic "hard" findings of arterial injury, including pulsatile bleeding, loss of distal pulses, an audible bruit or palpable thrill indicative of an AVF, or an expanding or pulsatile hematoma.[21] In addition, pallor or cyanosis and decreased temperature are common in a poorly perfused extremity, and massive distention of distal superficial veins may indicate an AVF as arterial flow is directed into distensible veins. The incidence of arterial injury in patients with any hard finding is consistently greater than 90%,[22,23] and the presence of these findings requires further investigation by emergency angiography or, more commonly, immediate surgical intervention, depending on the duration of warm ischemia and the overall status of the patient.

Soft Findings of Vascular Injury

An additional group of patients have "soft findings" of vascular injury, including a palpable but diminished pulse in comparison

www.ketabpezeshki.com 66485457-66963820

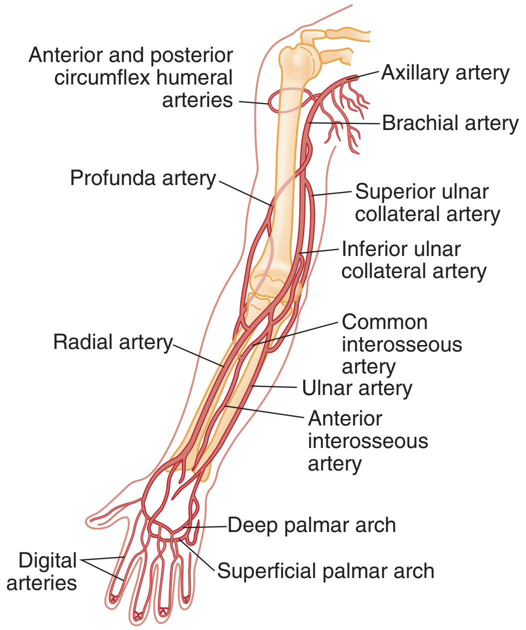

Figure 48-3. Major arteries of the upper limb. (From Snell R, Smith M [eds]: Clinical Anatomy for Emergency Medicine. St Louis, Mosby, 1993.)

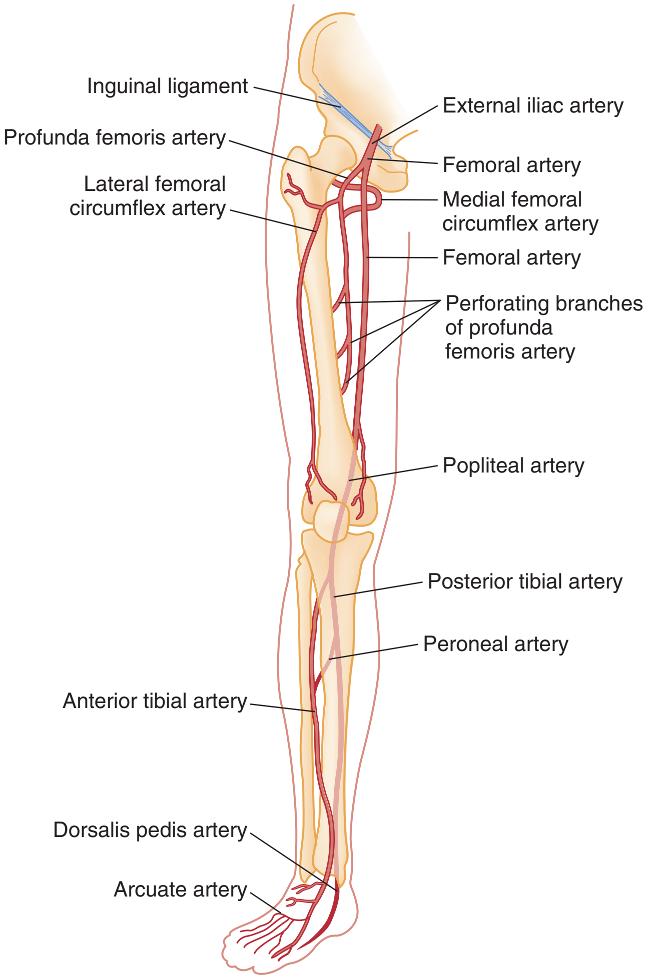

Figure 48-4. Major arteries of the lower limb. (From Snell R, Smith M [eds]: Clinical Anatomy for Emergency Medicine. St Louis, Mosby, 1993.)

with the uninjured extremity, isolated peripheral nerve injury, history of severe hemorrhage in the field, unexplained hypotension, or a large nonpulsatile hematoma.[21-24] The significance of prolonged capillary refill is controversial; some experts find it to be a reliable sign of vascular injury (when combined with a pulse deficit) and consider delayed capillary refill to be a valid "soft sign" of vascular injury. Others have found this sign to be a nonspecific and unreliable predictor of arterial injury.[5] Delayed capillary refill by itself is insufficient to diagnose arterial injury, but in combination with other physical signs it supports the diagnosis.

Isolated penetrating injury to a peripheral nerve is commonly associated with vascular injury because of the close proximity of these structures within the neurovascular bundles. Vascular injury occurs in 8 to 45% of cases of penetrating peripheral nerve injury.[25,26] Conversely, vascular injuries have associated peripheral nerve injury in almost half of cases. It is sometimes difficult to distinguish whether the pain, paresthesias, or paralysis is caused by a primary nerve injury, an associated vascular injury causing compression of the nerve, or compartment syndrome. In general, primary nerve injury occurs immediately at the time of injury, whereas vascular neuropathy occurs over minutes to hours after the injury. Up to 35% of patients with "soft" findings of vascular injury have positive angiographic studies, although only a small proportion of these injuries require emergency repair.[21,26,27]

High-Risk Injuries

The proximity of a penetrating wound to a neurovascular bundle is defined imprecisely. Various definitions include 1 cm, 1 inch, or 5 cm as constituting "proximity." Certainly, penetrating wounds that occur within 1 cm of a major neurovascular bundle or whose presumed trajectory has crossed such a bundle ("proximity wounds") are more likely to produce an occult vascular injury. Major neurovascular bundles include large limb arteries proximal to critical branch points, such as the axillary, brachial, common femoral, and popliteal arteries (Figs. 48-3 and 48-4).[28] In addition, a small minority of patients with high-risk injuries, such as bites from large dogs or other animals, shotgun wounds, severely displaced fractures, crush injuries, or major joint dislocations (especially knee dislocation), will initially have occult vascular injury that may not be detected on physical examination.[29] The risk of missing such injuries is that the traditional 6-hour window of warm ischemia time will be exceeded or the patient will experience delayed complications resulting in loss of the limb. For example, patients with intimal flaps may be completely asymptomatic initially but can subsequently develop arterial thrombosis. Similarly, pseudoaneurysms progressively enlarge to produce compression of adjacent structures but may be very small and undetectable on initial physical examination. Consequently, some centers routinely perform radiographic confirmation of arterial patency in these cases, although in most large-volume trauma centers current practice does not consider proximity alone as an indication for imaging.

History

In patients who achieve and maintain hemodynamic stability, a more comprehensive history can be obtained. Important historical points to note include the exact time and mechanism of the injury. The time of injury is important because of the significant morbidity that results from prolonged warm ischemia time. The mechanism is of clinical and often forensic importance in that the injury is frequently inflicted during an assault or other violent crime, in the context of domestic violence or physical abuse, or in association with work. Various mechanisms of injury may mandate special reporting and may alter the patient's ultimate disposition. Certain types of injuries, such as crush or bite wounds, are

www.ketabpezeshki.com 66485457-66963820

particularly prone to complications. The occupation, avocation, and hand dominance of the patient are pertinent because a more aggressive strategy may be indicated in certain cases. Medical conditions that pose a risk of complications are important to note. Patients who are immunocompromised because of diabetes, acquired immunodeficiency syndrome, asplenia, cancer, or steroid use are at increased risk for infection and impaired wound healing. Patients with previous vascular insufficiency have more tenuous perfusion, are more susceptible to ischemia from elevated compartment pressure, and have a higher incidence of complications. As with most aspects of trauma care, patients whose sensorium is altered by head injury or intoxication, patients with spinal cord injury who cannot perceive pain, and those with significant painful distracting injuries will not reliably be able to report pain or paresthesias suggesting vascular insufficiency, so extra caution is exercised in these cases.

Physical Examination

Surprisingly, in this era of increased reliance on technology, meticulous physical examination in combination with comparison of blood pressures in the affected and unaffected limbs has reemerged as the mainstay of diagnosis of vascular injury.[22] Physical examination is directed at discovering evidence of local wound complications and distal ischemia suggestive of vascular injury. Palpation of pulses in the affected extremities is the initial step. A comparison of the strength and quality of the pulses between the injured limb and its uninjured counterpart is then made. Isolated detection of a diminished pulse distal to the site of injury is a finding that merits further investigation rather than immediate surgery because palpation of pulses is a relatively inaccurate means of predicting arterial injury. False-positive findings of a pulse deficit may occur because of shock, in which all pulses are diminished; congenital absence of a pulse in one extremity; preexisting vascular disease; or arterial spasm or compression. A false-positive finding of a pulse deficit occurs in 10 to 27% of cases.[5,22,23] False-negative findings can occur with transmission of the pulse through a "soft clot," past an intimal flap, or through collateral circulation. Distal pulses can persist in 6 to 42% of patients despite significant arterial injury.[30] Compression of an artery by casts, splints, or dressings may produce a pulseless extremity, and these should be removed if evidence of ischemia occurs. Finally, although the pulse may be absent, the limb may be well perfused by collateral arterial supply, thus making immediate repair of the arterial injury less compelling. Simultaneous palpation of the injured and unaffected limbs can detect relatively small differences in skin temperature that may suggest hypoperfusion. Testing two-point discrimination on the injured and unaffected limbs is similarly an effective means of detecting sensory deficits. Auscultation over the site of injury is an often-ignored examination that may reveal a bruit suggestive of an AVF. A bruit is audible in more than half of patients with an AVF.[31] Repeated examination of the hematoma adjacent to the wound is indicated during the first 24 hours to determine whether it is expanding or pulsatile.

Despite the limitations just noted, reliance on the history and physical examination to triage patients into immediate surgery, imaging studies, and observation groups has been found to be relatively dependable, with a sensitivity of 92% and a specificity of 95%.[22] However, studies of military casualties injured by blast injury or high-velocity gunshot wounds have found physical examination to be less reliable than in studies of civilian casualties.[32]

DIAGNOSTIC STRATEGIES

The diagnostic strategy for detection of peripheral vascular injury is tailored to the clinical situation. Patients with clearly evident major arterial injury (e.g., pulsatile hemorrhage from a penetrating wound with a cold, pulseless distal end of the extremity) may require emergency operative intervention without the potential benefit of any ancillary confirmation of their injury. Occasionally the use of an intraoperative angiogram may be helpful in delineating the exact location and nature of the injury in patients taken directly to the operating room, especially if there are multiple potential sites of injury. However, delaying definitive treatment of an obvious arterial injury that is approaching the 6-hour limit of warm ischemia time to obtain an angiogram is ill advised.

Plain Radiography

Plain radiographs of the affected extremity are indicated to detect fractures, joint penetration, and foreign bodies. With gunshot wounds, the sum of the number of intact bullets seen on radiographs and the number of entrance and exit wounds in the body should be an even number. Failure to locate a bullet can result in unexpected complications. Rarely, bullets or shotgun pellets can migrate distally and produce vascular occlusion or migrate proximally through the venous system to the heart. These emboli are readily detected on plain radiographs if the search is vigilant.[33,34] Lead bullets retained within a synovial joint can result in systemic absorption and elevated lead levels and should be removed electively.[35-41]

Pulse Oximetry

Several relatively simple noninvasive maneuvers can be performed at the bedside to elicit evidence of arterial injury. The use of pulse oximetry has been suggested as a means of identifying limb ischemia after trauma, but it has been found to be relatively insensitive for this purpose. Clearly, in the absence of a pulse, no reading can be obtained. As the technology of transcutaneous measurement of physiologic indices advances, measurement of tissue oxygenation by near-infrared spectroscopy (NIRS) to quantify muscle oxyhemoglobin may prove more useful in detecting vascular injury because these devices are portable, noninvasive, and simple to use and appear to provide more accurate information than pulse oximetry.[42-47] Thus far, however, small clinical studies have found contradictory results in use of NIRS for this indication.[48,49]

Hand-held Doppler

An inability to palpate pulses in an injured extremity should be verified by auscultation with a hand-held Doppler unit. Apart from the absence of any signal, arterial injury may be suggested by a change in the usual triphasic quality of the Doppler pulse to a biphasic or monophasic waveform as the pulse is "damped" by partial occlusion. Although Doppler is more sensitive, auscultation of the pulse by this method is subject to the same types of limitations as is palpation of the pulse.

Ankle-Brachial Index and Arterial Pressure Index

In an effort to improve on the accuracy of physical examination without relying on expensive and invasive tests such as arteriography, the use of blood pressure in the injured versus the uninjured extremity (arterial pressure index [API]) or the blood pressure in an injured leg at the ankle compared with brachial artery pressure (ankle-brachial index [ABI]) was developed and validated in numerous studies as an accurate means of detecting vascular injury. Systolic pressure is measured by inflating a standard blood pressure cuff proximal to the injury and recording hand-held Doppler systolic pressure distal to the injury. The

www.ketabpezeshki.com 66485457-66963820

process is repeated on the uninjured limb, and a ratio of injured to uninjured systolic pressure is calculated (API). In general, a ratio less than 0.90 is considered abnormal and is an indication for further investigation. In several studies, an API less than 0.90 yielded a sensitivity of 95%, specificity of 97%, positive predictive value of 100%, and negative predictive value of 95%.[5,21,50-52] However, a few studies have found API to be less accurate, including one in which a cutoff of 0.90 resulted in a false-negative rate of nearly 40%; nevertheless, the use of an API ratio less than 0.90 can eliminate a large number of unnecessary angiograms for proximity wounds and increase the diagnostic efficiency of angiography or computed tomographic angiography (CTA) by limiting its use to high-yield cases.

Patients with an API of 0.90 to 0.99 merit observation for 12 to 24 hours for repeated physical examination and API measurements to detect evolving injury. Patients with normal physical examination findings and a completely normal (>0.99) ABI can be safely discharged from the emergency department provided there are no other injuries requiring admission.[52]

Exclusive reliance on API to screen for arterial injury has significant limitations. Comparisons cannot be made when both limbs are injured or when severe soft tissue mangling precludes placement of a blood pressure tourniquet or location of the artery to be measured with the Doppler unit.[21] As with physical examination, the sensitivity of API is limited when an intimal flap allows near-normal flow or when collateral circulation is sufficient to produce near-normal systolic pressure, as in proximal injuries to the subclavian or iliac vessels. Certain arteries (e.g., the profunda femoris, profunda brachii, and peroneal arteries) normally do not produce palpable pulses, and API is of limited usefulness in these injuries. Shotgun wounds often are associated with normal APIs despite multiple small arterial wounds; catheter-based angiography is the preferred diagnostic modality in this group. As with formal angiography, API cannot detect venous injuries.

Despite the limitations previously noted, API has proved effective in screening patients with proximity wounds. The vast majority of injuries missed by API heal spontaneously. Those that do not heal are generally seen within 3 months with signs of arterial injury and can be repaired electively.

Ultrasound

The development of relatively small portable ultrasound (US) units has made possible direct visualization of both arterial and venous flow in major vessels. There are several different types of US that can detect vascular injury, and newer, more accurate techniques are being developed rapidly. B-mode (real-time) US is the most readily available form of US in portable units. It can easily visualize arterial pulsation in major vessels. Loss of pulsation distal to an obstruction or thrombosis is readily apparent. However, B-mode US cannot visualize certain anatomic areas accurately (subclavian and iliac vessels) because of overlying pulmonary tissue, and it is unreliable in detecting a fresh, relatively nonechogenic thrombosis or hematoma. As blood liquefies within a hematoma, it becomes echolucent and more readily distinguishable from surrounding tissues.

Doppler US interprets sound moving toward or away from the transducer as flow. Venous flow is heard as a low-pitched hum, whereas arterial flow has a higher-pitched triphasic quality. The combination of B-mode and Doppler US is called *duplex US* and has enhanced accuracy in examining blood vessels. Duplex scans showing a focal increase in peak systolic velocity suggest partial obstruction of the vessel. However, duplex scanning is slightly less accurate in detecting injuries that do not decrease flow, such as small pseudoaneurysms, AVF, and intimal flaps.[53] Also, it is technically limited in examining certain anatomic areas, such as the profunda femoris and profunda brachii arteries and the iliac and subclavian vessels. Duplex US findings may be subtle, and as with other applications of US, its accuracy is highly operator dependent. Despite these limitations, the sensitivity of duplex US in comparison with standard angiography ranges from 83 to 100%, with a specificity of 99 to 100% and an accuracy of 96 to 100%.[21,53,54]

Color flow Doppler converts Doppler echoes into quantitated visual signals. Flow toward the transducer is seen as red, and flow away from the transducer is seen as blue. The intensity of the color (the number of pixels on the screen) is proportional to flow through the vessel. Small prospective studies have indicated a high rate of accuracy in detecting arterial injury.[53,54] Absence of flow is readily apparent, but more subtle injuries, such as intimal flaps and small pseudoaneurysms, are more difficult to identify. In addition, color flow Doppler is more accurate than standard venography in detecting major venous injuries. The overall sensitivity of color flow Doppler in detecting arterial injury is 50 to 90%, with a specificity of 95 to 99%. The sensitivity for detecting injuries requiring surgical repair is greater than 90%.[23,53,54] The use of intravascular US for examination of abdominal aortic aneurysms has been well documented. Although not yet applicable to smaller peripheral vessels, with further reduction in size of the transducers, this technique may eventually be applicable for peripheral vascular injury as well.

Computed Tomography and Magnetic Resonance Imaging

With a few important exceptions, computed tomography (CT) with contrast enhancement (CTA) has largely replaced catheter-based angiography for the detection of peripheral vascular injury in most trauma centers. Multidetector helical CT (MDCT) scanners have proven very accurate for diagnosis of peripheral vascular injury in multiple series with a sensitivity of 93 to 100% and specificity of 87 to 100% compared with catheter-based angiography.[2,55-72] The advantages of CTA over catheter-based angiography are that it is noninvasive, readily available, and less costly and provides information on other injuries in the region being studied. However, there are several pitfalls to the use of MDCT angiography. Metallic artifact from bullets, orthopedic hardware, or other penetrating objects may obscure visualization of parts of a vessel, although with image reconstruction techniques, this problem can be largely overcome.[62] Venous injuries may be missed depending on the phase of the contrast.[62] The rapid image acquisition of current CT scanners makes timing of the contrast bolus more critical, and out-of-phase images may miss arterial injury. In practical terms, though, CTA is very useful in that it can be integrated into an overall plan for diagnostic imaging, including CT of the head and trunk, all of which can be accomplished rapidly.[69] Because of the enhanced detail, accuracy, and speed of image acquisition with 64- to 256-slice CT scanners and the ability to perform three-dimensional reconstructions, this modality has become the standard imaging technique for suspected vascular injury. Magnetic resonance angiography (MRA) has been described and accurately detects vascular injuries but has yet to prove clinically useful.[73] MRI is also contraindicated in the presence of iron-containing metallic foreign bodies.

Arteriography

The policy of routinely exploring proximity wounds greatly improved the preservation of injured limbs in World War II. With the advent of arteriography and digital subtraction angiography (DSA), it became apparent that many negative wound explorations could be avoided with routine arteriography. In a study using routine arteriography, the negative surgical exploration rate

www.ketabpezeshki.com 66485457-66963820

in patients with soft signs of arterial injury or with proximity wounds decreased from 84 to 2%.[74] As a result, until recently, catheter-based contrast angiography has been the gold standard for diagnosing peripheral arterial injury, with a sensitivity of 99% and specificity of 97%.[21]

Beginning in the 1980s, the number of civilian penetrating wounds increased dramatically. Because of high cost, limited availability at all hours, and poor reimbursement rates, the policy of routine arteriography for proximity wounds has been questioned. From a practical perspective, the time required to mobilize the angiography team and perform the study may be several hours, thus making this option less desirable when dealing with the time limitations posed by arterial injury. In addition, arteriography has a small but measurable complication rate, including allergic reactions to contrast media, renal complications, hematoma formation, and false aneurysm formation at the site of cannulation. Finally, the clinical usefulness of the information provided by arteriography has become increasingly suspect in recent years as more of these injuries have been managed expectantly. Routine "exclusion" arteriography for proximity wounds detects unsuspected arterial injury in 0 to 21% of cases.[27,75-77] However, relatively few of these patients require emergency surgery. In a series of 284 patients who underwent routine angiography for proximity wounds, 17% had unsuspected arterial injury detected, but only 1.8% (five patients) required emergency surgical repair.[76] In other series reporting on a total of 483 patients who underwent angiography for proximity wounds, only one arterial injury that required emergency repair was discovered.[74-78] In the presence of soft signs of injury other than proximity, the yield for angiograms increases to 29 to 35%, but many of these injuries do not require emergency repair and can be detected by noninvasive means.[76] In addition, angiography results in an approximately 5% false-positive and false-negative rate compared with surgical exploration. Many of the injuries detected on angiography are caused by reversible vasospasm or very small intimal defects that generally heal spontaneously. Consequently, angiography for proximity wounds can detect injury in up to 21% of cases but results in acute surgical intervention in only 0 to 4.4% of cases.[74] Many centers now successfully manage proximity wounds by repeated physical examination over a 24-hour period and reserve CTA for those with abnormal physical findings or an ABI less than 0.9.[78-82] Angiography is also limited in that it cannot detect major venous injuries, which are increasingly being repaired surgically. The use of angiography is difficult in children because of the small caliber of their vessels and a propensity for vasospasm induced by angiography. Consequently, physical examination and noninvasive methods are preferred for detection of vascular injury in young children.[77]

DSA has been used for detecting vascular injuries as well. DSA has been found to be more accurate than standard angiography for detection of extravasation and has the advantage of requiring the administration of a smaller load of contrast material. However, the field of view is much smaller with DSA than with standard angiography, thus making it technically difficult to study the entire course of a limb artery with DSA. Standard angiography is also more accurate than DSA in detecting intimal flaps and dissection. Traditional catheter-based angiography has the advantage over other diagnostic techniques in that it can also be used to treat many lesions. Embolization of pseudoaneurysms, endovascular stent insertion to bypass a dissection or AVF, and injection of thrombolytic agents to dissolve thrombus are routinely performed via intra-arterial catheter. Because of increased reliance on endovascular treatment, many of the lesions detected by other means ultimately still require angiography.[69] Intraoperative angiography is often used as a primary study in patients with hard findings of vascular injury to delineate the extent of the damage to the vessel and plan operative repair.

TREATMENT

Initial treatment is directed at ensuring a patent airway and adequate air exchange before assessing the circulation. Once this has been accomplished, active hemorrhage is controlled by direct digital pressure. Blind clamping of a bleeding vessel is not recommended because of the risk of crushing adjacent nerves; however, clamping a clearly visible vessel can be effective. The use of tourniquets has been generally discouraged because of compression nerve palsies, occlusion of veins resulting in increased compartment pressure, and an increased risk of venous thrombosis.[5] However, recent reports in the military literature state that the use of tourniquets for up to 6 hours is safe, effective, and lifesaving in some cases.[83] Tourniquets should be applied if direct pressure is insufficient to control bleeding and left in place until definitive surgical control can be achieved. In the military studies, there were few complications associated with the use of tourniquets, and almost all of these were transient. In cases in which proximal and distal control of large-vessel injuries cannot be readily achieved in the emergency department, insertion of a Foley catheter into the wound and inflation of the balloon with sterile water can temporarily tamponade the bleeding. Intravenous lines should not be started in the injured extremity because they may be ineffective in delivering resuscitation fluid or medication and because extravasation from an injured vein may increase compartment pressure. Serial hemoglobin determinations may indicate unexpected blood loss from occult vascular injury. Patients with significant blood loss should have blood typed and crossmatched and may require immediate transfusion for stabilization. Patients with significant vascular injury often remain hypotensive despite such infusion and require further volume infusion or blood transfusion. Moribund patients with multiple severe injuries may require urgent amputation as part of their overall stabilization or extrication from wrecked automobiles or collapsed buildings. Between 50 and 70% of patients with severely mangled limbs require urgent amputation, especially if they have multisystem trauma.[84]

The issue of "hypotensive resuscitation" is controversial with regard to major vascular injuries. A tenuous clot can form in injured arteries and prevent further blood loss as long as the patient remains hypotensive. Once arterial pressure reaches a critical but variable point, the clot may be expelled and massive blood loss can ensue. Therefore when the arterial injury is inaccessible for occlusion by direct pressure, the target blood pressure for resuscitation should be lowered to a systolic pressure of approximately 90 mm Hg. Overly aggressive and rapid fluid administration in the field or in the emergency department can produce transient intravascular hypervolemia and may ultimately increase the rate of blood loss. Close monitoring of vital signs and the total volume of fluid infused is indicated in these situations.[85]

Once a vascular injury has been identified, a specific diagnostic and therapeutic strategy can be developed that is consistent with the severity of the injury, the presence of other injuries, and the resources available. In hospitals without the ability to perform vascular repair, transfer to a trauma center should be initiated early. In cases in which the transfer will involve a delay of several hours, cooling the ischemic limb will avoid exceeding the critical 6-hour cutoff for warm ischemia. For this to be accomplished, the limb is wrapped in towels, and ice in plastic bags is applied around the limb, avoiding direct contact of the ice to the limb, which can result in frostbite.

Major Vascular Injuries

Major vascular injuries that compromise the viability of a limb should be repaired within 6 hours to avoid irreversible ischemic neuropathy and myonecrosis.[5] Treatment of vascular injury has changed dramatically in the past 10 years. Endovascular treatment

www.ketabpezeshki.com 66485457-66963820

with self-expanding stents is currently the preferred technique for repair of these injuries in stable patients, and the majority of arterial repairs in the United States are now done with this technique.[86-88] In hemodynamically unstable patients, open surgical repair is still preferred. If other life-threatening injuries must be repaired first, a temporary polytetrafluoroethylene (PTFE) vascular shunt can be placed in the operating room to restore perfusion to a limb.[89] These temporary PTFE shunts can be left in place for up to 24 hours before thrombosis begins to occur within the shunt. Major arterial transection or thrombosis is ideally repaired by end-to-end reanastomosis, if possible, without placing undue tension on the suture line. If a larger segment of the artery is destroyed, interposition of a reverse saphenous vein graft is the preferred technique. PTFE grafts are suitable for grafting larger arteries if necessary, but they tend to occlude when used in smaller arteries (e.g., distal to the femoral or brachial arteries). Before completion of the reanastomosis, a Fogarty catheter is passed through both ends of the repair to extract any thrombi that may have formed. The distal circulation is flushed with a dilute 1:10 solution of heparin or enoxaparin to prevent early clot formation. Systemic administration of heparin is usually contraindicated in patients with major trauma. Assessment of distal perfusion and, in particular, compartment pressures is indicated frequently after repair and reperfusion of the limb. The use of broad-spectrum antibiotics is recommended before commencement of vascular repair.

Apart from excision of the affected arterial segment and repair of the vessel, less invasive techniques have been developed to manage pseudoaneurysms. Percutaneous embolization with Silastic beads, gel clot emboli, or thrombogenic coils is often successful in excluding the pseudoaneurysm.[90] Placement of an endovascular stent can exclude the aneurysm and is also a successful alternative to open repair.[91] Similarly, repair of an AVF can be undertaken through open surgical ligation of the fistulous connection, by endovascular placement of a stent to exclude the fistula, or by percutaneous embolization of the fistulous tract.[90]

Late Complications

Despite timely optimal repair of arterial injuries, approximately 21% of patients experience delayed complications requiring further surgical intervention, including delayed amputation. The most common of such complications is delayed thrombosis, which often occurs after many months as stenosis at the repair site progresses. Other complications include intermittent claudication, chronic pain or edema of the limb, and aneurysm formation in the graft.[92]

Venous Injuries

Venous injuries may be primarily ligated if the condition of the patient cannot tolerate prolongation of surgery. However, the current trend is to repair major venous injuries if possible, particularly in the lower extremity, because wound healing is improved and the incidence of compartment syndrome, venous thrombosis, pulmonary embolism, and chronic edema is decreased.[92-95] Extensive venous collaterals in the upper extremity make surgical repair less compelling.

The timing of repair of a vascular injury when associated with complex fractures requiring fixation is controversial. Historically, the fracture was repaired first to give a more accurate measurement of limb length and the length of graft required for vascular repair and because of fear that manipulation of long bones during reduction might damage the vascular repair. However, the need for postoperative fasciotomy is higher in these patients than in those who undergo vascular repair first (80% vs. 36%), and vascular repair is limited by warm ischemic time.[96] Currently in most centers, vascular repair is prioritized over orthopedic repair, although temporizing PTFE shunts may be used to restore perfusion during fracture repair.

Minor Vascular Injuries

Increasingly, minor nonocclusive vascular injuries are being treated expectantly. Criteria for observation of vascular injuries include low-velocity missile wounds, intact distal circulation, absence of active hemorrhage, and minimal arterial wall disruption on angiography if performed. Angiographic or CTA findings meeting these criteria include intimal flaps extending less than 5 mm and pseudoaneurysms smaller than 5 mm in diameter.[5] Follow-up of these injuries with repeat angiography or US reveals that approximately 85% resolve spontaneously.[68] Patients meeting these criteria can be monitored as outpatients for 3 months, with repeat physical examination and US to detect delayed complications.[27,76,97] However, almost all pseudoaneurysms ultimately require repair and, once discovered, should be repaired electively rather than undergoing continued observation. Failure to detect and repair occult arterial injuries in children often results in severe differential limb growth, and thus a more aggressive policy of repairing any arterial injury that causes even a relatively minor decrease in blood flow to a child's growing limb may be justified.

SPECIFIC INJURIES

Upper Extremity

Subclavian Artery and Vein

Subclavian artery injuries are uncommon and represent 1 or 2% of all vascular trauma.[98] Isolated injury to the subclavian vein is more common than isolated arterial injury, but in almost half the cases both the vein and the artery are injured.[99] The vast majority (95-99%) are penetrating wounds, and because of massive hemorrhage, these injuries are often lethal before arrival at a hospital. Mortality in those who reach the hospital alive averages 15%, but overall mortality as high as 75% has been reported.[100-104] It is interesting to note that morbidity is higher with a blunt mechanism, whereas mortality is higher with penetrating wounds.[101] The right subclavian artery arises from the brachiocephalic artery, and the left arises from the arch of the aorta. From their origin, they course posterior and inferior to the clavicles to the outer margins of the first ribs, where they become the axillary artery and vein. The left subclavian artery rises higher than the right and extends into the root of the neck.[28]

The clinical manifestation is that of hemorrhagic shock in 77% of cases. Occasionally, unsuspected subclavian vascular injury is discovered at thoracotomy performed for excessive blood loss from a chest tube.[99] Approximately 60% have an associated pneumothorax or hemothorax, and additional injury to mediastinal and spinal structures is relatively common.[98] Symptoms of limb ischemia may be apparent with absent radial and brachial pulses. However, pulses are completely absent in only 33% of cases because collateral flow from the thyrocervical trunk may provide sufficient perfusion to avoid the symptoms and signs of ischemia.[99] Neurologic deficits in the upper extremity occur in more than half of patients. The most severe of these injuries is damage to the brachial plexus, which occurs in almost 50% of patients with blunt injury.[99]

In a series of 100 cases of subclavian artery injury, the combination of physical examination and chest x-ray findings suggestive of subclavian injury (hemothorax, pneumothorax, apical pleural cap, or wide mediastinum) was 100% sensitive and could have eliminated the need for 69% of the arteriograms obtained.[101] If the patient's clinical condition permits, however, angiography can

www.ketabpezeshki.com 66485457-66963820

provide an accurate diagnosis and can locate the injury precisely. APIs are relatively inaccurate with proximal thoracic outlet injuries because of collateral arterial flow. US techniques are also relatively inaccurate in detecting subclavian injuries because of interference by overlying gas-filled lung tissue. Therefore in cases in which the clinical diagnosis is equivocal (soft signs of injury or proximity wounds), arteriography (CTA or catheter based) is required to detect the injury. Immediate proximal and distal control of the subclavian artery is very difficult. An incision along the course of the clavicle is recommended but often needs to be extended to a sternotomy.[67] If primary reanastomosis is not possible, synthetic grafts are usually successful but have a tendency to fracture over time owing to the wide range of motion at the shoulder and resultant compression of the graft by the first rib and clavicle.[105]

Blunt subclavian injuries are often associated with clavicular fracture or dislocation. Isolated first rib fracture is rarely combined with vascular injury unless posterior displacement occurs. However, first rib fracture in association with other major injuries, such as a wide mediastinum on the chest radiograph, an expanding hematoma, an upper extremity pulse deficit, or a brachial plexus injury, is accompanied by arterial injury in 24% of cases and merits investigation by angiography or CTA.[106] Several cases of shear injury of the subclavian artery have been reported to result from a loose shoulder restraint of a seat belt during a motor vehicle collision (MVC). Overall, blunt subclavian artery injuries have a higher morbidity than penetrating injuries because of higher rates of limb amputation and associated brachial plexus injury.[98]

Subclavian vein injuries are even more lethal than those to the artery. In addition to massive blood loss, there is a relatively high risk of massive air embolism, which is frequently fatal in association with penetrating subclavian vein injuries. Patients with known or suspected subclavian vein injury should be placed in Trendelenburg's and left lateral decubitus position to reduce the incidence of this complication.

Axillary Artery and Vein

Injury to the axillary vessels constitutes 3 to 9% of all vascular injuries, with penetrating mechanisms predominant.[107] Blunt injuries are associated with proximal humerus fracture or forceful reduction of a dislocated shoulder, particularly if chronically dislocated.[108] The axillary artery courses from the lateral border of the first rib to the inferior border of the teres major muscle, where it becomes the brachial artery. The axillary vein runs medial to the artery. The extensive anastomotic arterial connections around the shoulder joint usually permit good collateral flow,[28,99] and up to half of these patients will have palpable pulses as a result of collateral circulation.[109] Because of the close proximity of the brachial plexus and the axillary vessels, significant denervation of the upper extremity can occur. Near-avulsion injuries resulting in scapulothoracic dissociation invariably produce severe disruption of the brachial plexus and often ultimately result in amputation despite successful vascular repair. There is a high rate of amputation for the combination of axillary vascular and brachial plexus injury, mainly because the presence of a flail limb results in amputation for placement of a prosthesis.

Brachial Artery

The brachial artery continues from the lower border of the teres major muscle and divides into the radial and ulnar arteries at the level of the proximal aspect of the radial head. The median and ulnar nerves and the basilic vein are in close proximity to the brachial artery. The profunda brachii artery is a major branch that arises slightly after the origin of the brachial artery and often contributes good collateral flow if the brachial artery is injured distal to this branch point.[28,99] Brachial artery injuries occur as a result of penetrating trauma, humeral shaft fracture, elbow dislocation, or animal bites.[100] They are the most common major vascular injuries in the upper extremity. In 75% of cases the radial pulse is absent.[30] Studies have shown that limb salvage rates have improved to nearly 100% owing to efficient out-of-hospital transport, improved surgical techniques, and shorter time to first antibiotic dose.[110] Repair is indicated in all cases because the amputation rate is high with ligation.

Forearm Arteries

The radial artery begins in the cubital fossa and runs superficially to the distal end of the radius, where it ultimately joins the deep branch of the ulnar artery to form the deep palmar arch of the hand. The ulnar artery begins in the cubital fossa and runs with the ulnar nerve anterior to the flexor retinaculum, at which point it joins the radial artery to form the superficial palmar arch of the hand.

Injuries detected by arteriography or US that are below the bifurcation of the arterial supply in the upper extremity do not need to be repaired unless there are signs of ischemia in the hand; "hard signs" of arterial injury such as an expanding hematoma, pseudoaneurysm, or AVF; or injury to both radial and ulnar arteries. However, some authors recommend repairing all these injuries because of the risk of intermittent claudication or cold intolerance in patients who have one artery ligated. Certain patients are almost exclusively dependent on the ulnar arterial supply to the hand because of an underdeveloped deep palmar arch. Clearly, ulnar artery injuries should be repaired in these patients. Compartment syndrome in the forearm is common after repair of proximal arteries and veins and may require fasciotomy.

Lower Extremity

Iliac Artery and Vein

Given the intra-abdominal course of the iliac vessels, virtually all iliac artery and vein injuries have associated trauma to the small or large intestine, bladder, solid viscera, or bony pelvis. The common and external iliac arteries are injured with equal frequency and more often than the internal iliac vessels.[111] Approximately 80% of iliac vessel injuries are caused by penetrating trauma, and the remainder are mainly associated with pelvic fracture.[112] Trauma to the iliac veins is responsible for massive bleeding in displaced pelvic fractures and often requires angiographic embolization for control (see Chapter 55). In moribund patients, an initial "damage control" laparotomy with temporary vascular shunting of the iliac vessels is often necessary as resuscitation continues. After the patient has overcome lactic acidosis, hypothermia, and coagulopathy, a second definitive repair can be undertaken. It is surprising to note that the incidence of infection of synthetic or autologous grafts is rather low despite the high degree of bacterial contamination associated with perforation of a hollow viscus. Distal ischemic complications occur with approximately one third of repaired iliac arteries, and subsequent amputations are required in up to 18%.[111]

Femoral Artery and Vein

The external iliac vessels become the common femoral vessels at the inguinal ligament. After giving off the profunda femoris artery in the femoral triangle, the femoral artery continues as the superficial femoral artery almost vertically to the adductor tubercle of the femur and enters the popliteal fossa as the popliteal artery. There are extensive proximal collaterals around the hip joint,

www.ketabpezeshki.com 66485457-66963820

including the gluteal, obturator, and pudendal branches of the iliac artery.[28]

Femoral artery and vein injuries are the most common vascular injuries seen in major trauma centers. Common femoral artery injury occurs as a result of intertrochanteric hip fracture, hip dislocation, and iatrogenic injury from the placement of arterial catheters or from hip replacement surgery, although 86% of femoral artery injuries are caused by penetrating wounds.[113] Ligation of the common femoral artery culminates in amputation of the lower extremity in 80% of cases, so repair should be attempted in all cases. Penetrating wounds of the thigh result in femoral artery injury in 6.2% of cases, and up to 40% of these injuries are clinically occult. A medial or anteromedial wound track is present in virtually all these cases, and CTA has proven highly accurate in diagnosing these injuries and has largely replaced other imaging techniques.[114-116]

Popliteal Artery and Vein

The popliteal artery gives off the genicular branches in the popliteal fossa and then divides into the anterior and posterior tibial arteries at the lower border of the popliteus muscle. The peroneal artery arises from the posterior tibial artery slightly after its origin. The anterior and posterior tibial arteries and the peroneal artery form the trifurcation of the popliteal artery, and each runs with a corresponding vein and nerve in different compartments of the leg.[28]

The most common cause of popliteal artery injury is posterior knee dislocation in which bony elements directly lacerate or cause thrombosis of the artery. Displaced fractures of the knee, particularly tibial plateau fractures, may also result in popliteal artery injury. Anterior knee dislocations may cause excessive stretch on the popliteal vessels that can culminate in arterial thrombosis, but this injury is relatively rare. Overall, knee dislocation results in popliteal artery injury in 25 to 33% of cases.[117] Up to 40% of these injuries may be clinically occult, and diagnosis is delayed in up to 40% of cases,[2] although other series note that more than two hard signs of ischemia occur immediately in 71 to 94%.[4,5] Twenty-five percent of cases have an associated injury to the peroneal and posterior tibial nerves. In half the cases, the knee dislocation may reduce spontaneously, leaving little evidence of the original trauma, particularly in obtunded patients.[101] Patients showing complete ligamentous disruption of the knee on physical examination should be suspected of having a spontaneously reduced knee dislocation. Hemarthrosis may also be absent if the joint capsule is torn because blood can track into the fascial planes of the leg.

No consensus has been reached on the diagnostic approach to detect popliteal artery injury resulting from documented or suspected knee dislocation. There are three possible strategies, and each has proponents and detractors. The first option is to perform routine arteriography on every case of knee dislocation.[118,121] The second is to perform CTA or arteriography on selected cases in which vascular injury is not certain despite the combination of physical signs, abnormal ABI measurement, or findings on noninvasive tests such as color flow Doppler or duplex scan.[121] The third option is to rely completely on these physical findings and ABI to exclude arterial injury. If both these findings are normal, advocates of this approach claim 100% negative predictive value for vascular injury that requires surgery.[51,80,82,122,123] The choice of these options is institution specific, but most centers continue to use angiography in selected cases. Abnormal ABI and US (duplex and color flow Doppler) have been found to be very accurate in detecting popliteal injuries, and many centers reserve angiography or CTA for cases in which noninvasive tests result in equivocal findings. As a general rule, high-energy mechanisms of trauma (e.g., auto vs. pedestrian and MVC) and posterior knee dislocations are more likely to produce popliteal artery injury than are low-energy mechanisms (e.g., sports injuries), and a more aggressive diagnostic approach (i.e., angiography or CTA) may be warranted in such cases. However, patients with *penetrating* trauma and more than one hard sign of popliteal artery injury can be taken directly to the operating room for repair because delaying these cases to obtain an angiogram is "superfluous, unnecessary, costly, and potentially dangerous."[106] Patients with *blunt* trauma can have false-positive hard findings generated by soft tissue swelling and external arterial compression, and these patients should undergo diagnostic testing first to confirm arterial injury. The amputation rate for popliteal injuries was as high as 40% in the past, but current rates are lower. In one large series, the amputation rate was 20%, but a high rate of permanent disability was found at 2-year follow-up.[124] Another series reported no amputations with modern diagnostic and repair techniques.[5,106] Factors that place patients at higher risk of amputation include severe mangling of the extremity, the presence of multiple fractures, major venous repair, or delay in repair exceeding 6 hours of warm ischemia time.[119] Because of the high incidence of compartment syndrome with lower leg injuries, fasciotomy is required in 49% of cases, and some centers routinely perform fasciotomy in all such cases.[125] Approximately two thirds of patients with popliteal artery injury will have persistent deficits caused by peripheral nerve injury, chronic ischemia, or amputation.

Lower Leg Arteries

The popliteal artery divides into three branches—the anterior and posterior tibial and the peroneal arteries at the inferior margin of the popliteal fossa. Injuries below the trifurcation at the knee may need repair if hard signs of arterial injury are apparent in the foot or if two of the three arteries are occluded on angiography.[27] However, vascular injuries in the lower part of the leg are notorious for causing compartment syndrome and need to be monitored closely. Amputation is usually a result of a combination of soft tissue, nerve, and bone injuries. If significant injury to all three of these tissues is present, the amputation rate may reach 54%.[27,126] The combination of orthopedic and vascular injury, particularly as a result of crush injury, and shock on initial evaluation culminates in amputation in 35% of cases and should be considered a poor prognostic sign for limb viability.[110]

DISPOSITION

Patients with confirmed injury to major vessels, equivocal findings on diagnostic tests, or symptoms of limb ischemia are admitted to the hospital for further investigation or observation. Consultation with a vascular surgeon is indicated as soon as vascular injury is strongly suspected or the need for emergency operative repair established. Patients who are unstable because of vascular or other injuries may undergo further investigation or exploration in the operating room. If the treating hospital is incapable of performing vascular surgery or appropriate investigations, transfer to a trauma center should be initiated. Delaying transfer for angiograms of proximity wounds in centers that are incapable of acting on positive results is unwise because it often delays definitive care beyond the safe limits of warm ischemia time.

www.ketabpezeshki.com 66485457-66963820

KEY CONCEPTS

- The overall condition of the patient determines the extent of diagnostic study and stabilization in the emergency department. Critically injured patients may require immediate surgery, which should not be delayed for confirmatory study of obvious vascular injury.
- Arterial injury may be readily apparent or clinically occult. Up to 21% of proximity wounds show arterial injury only on angiography, although few of these require emergent surgery. Similarly, various US modalities and abnormal APIs frequently detect clinically unapparent vascular injuries.
- Symptoms of arterial injury may be delayed by hours to months after the initial injury. Late onset of symptoms suggests delayed thrombosis, pseudoaneurysm or AVF formation, compartment syndrome, or intermittent claudication resulting from stenosis or reliance on small-caliber collateral vessels for arterial perfusion.
- Reperfusion injury can occur after restoration of arterial flow and result in compartment syndrome. Frequent reexamination of the reperfused limb is indicated in the postoperative period.
- Compartment syndrome frequently develops in limbs with arterial injury, and fasciotomy is often required.
- CT angiography is playing an increasing role in the diagnosis of vascular injury and essentially replaced catheter-based angiography for all but a few indications.
- Many vascular injuries are amenable to endovascular treatment with self-expanding stents. This results in fewer complications, lower cost, and earlier discharge from the hospital.

Chapter 49

General Principles of Orthopedic Injuries

Joel M. Geiderman and Dan Katz

MANAGEMENT PRINCIPLES

Patients with orthopedic injuries and nontraumatic musculoskeletal disorders compose a large portion of the more than 100 million patients who come to U.S. emergency departments (EDs) annually. Although only rarely life-threatening, orthopedic injuries may threaten a limb or its function, and accurate early diagnosis and treatment can avert long-term complications. Many of these injuries can and should be treated definitively by the emergency physician. Consultation with an orthopedist should be sought for the treatment of most long bone fractures, open fractures, injuries with joint violation, and injuries with neurovascular compromise and for follow-up of certain patients initially treated in the ED.

Orthopedic injuries often occur as a result of accidents (industrial or otherwise) and frequently involve young, otherwise healthy, working individuals. Accurate initial diagnosis, treatment, and documentation assume great importance medically and economically. Many problems can be avoided if the following 10 general principles are kept in mind:

1. Most orthopedic injuries can be predicted by understanding the chief complaint, the age of the patient, the mechanism of injury, and an estimate of the amount of energy delivered.
2. A careful history and physical examination predict radiographic findings with a high degree of accuracy. A presumptive diagnosis before a radiographic study may prompt the physician to order special views necessary to correctly diagnose an injury. Many fractures were accurately described before the advent of roentgenology (Table 49-1).
3. If a fracture is suggested clinically, but radiographic films appear negative, the patient should initially be treated with immobilization as though a fracture were present.
4. Criteria for adequate radiographic studies exist; inadequate studies should not be accepted.
5. Radiographic studies should be performed before most reductions are attempted, except when a delay could be potentially harmful to the patient or in some field situations.
6. Neurovascular competence should be checked and recorded before and after all reductions and after application of immobilization.
7. Patients must be checked for the ability to safely ambulate before discharge from the ED and should not be discharged unless this can be established.
8. Patients should receive explicit aftercare instructions before leaving the ED, covering such areas as monitoring for signs of neurovascular compromise or increasing compartment pressure, cast care, weightbearing, crutch use, and an explicit plan and timing for follow-up.
9. In a patient with multiple trauma, noncritical orthopedic injuries should be diagnosed and treated only after more threatening injuries have been addressed.
10. All orthopedic injuries should be described precisely and according to established conventions. When communicating with an orthopedic consultant, this may affect decisions regarding disposition of a patient and operative versus nonoperative management.

FRACTURES

Fracture Nomenclature

Describing orthopedic injuries with precise language according to established convention enables accurate, clear communication with other parties. Terms commonly used to describe a fracture are listed in Box 49-1. A fracture is a break in the continuity of bone or cartilage. Clinically, a history of loss of function, pain, tenderness, swelling, abnormal motion, and deformity suggests a fracture. Radiographic studies are the mainstay of diagnosis and are usually, although not always, confirmatory. At times, use of special views, radionuclide bone scans, computed tomography (CT), or magnetic resonance imaging (MRI) is necessary to confirm a clinical impression. These studies should be considered when the clinical evidence is at odds with the findings of routine radiography.

General Descriptors

Description of a fracture should begin by stating whether the fracture is *closed* or *open* (less desirable terms are *simple* or *compound*). In a closed fracture the skin and soft tissue overlying the fracture site are intact. The fracture is open if it is exposed to the outside environment in any manner. This exposure may be as obscure as a puncture wound or as gross as splintered bone protruding through the skin. It is sometimes difficult to determine whether a small wound in proximity to a fracture actually communicates with that fracture. Some physicians advocate probing such a wound with a blunt sterile swab to establish a relationship; no study has established the safety, benefit, or accuracy of this maneuver. If doubt exists, an open fracture should be assumed to be present.

The next item that should be noted in the description of a fracture is the exact anatomic location, including the name of the bone, left or right, and standard reference points along the bone, for example, the *humeral neck* or *posterior tibial tubercle.* Long bones can be divided into thirds—proximal, middle, or

www.ketabpezeshki.com 66485457-66963820

Table 49-1 Common Fracture Names and Their Origins

FRACTURE EPONYM OR NAME	DESCRIPTION	COMMENT
Aviator's	Vertical fracture of the neck of the talus with subtalar dislocation and backward displacement of the body.	First described in flyers during World War I. Arises from forced dorsiflexion of the foot in flying accidents and in traffic accidents after a head-on collision.
Barton's	Intra-articular fracture-dislocation of the wrist.	Considered complicated and unstable. Requires surgical reduction in most cases. Described by Barton in 1838 before the advent of radiography.
Dorsal Barton's	Oblique intra-articular fracture of the dorsal rim of the distal radius with displacement of the carpus along with the fracture fragment.	Results from high-velocity impact across the articular surface of the radiocarpal joint, with the wrist in dorsiflexion at the moment of impact.
Volar Barton's	Wedge-shaped articular fragment sheared off the volar surface of the radius (volar rim fracture), displaced volarly along with the carpus.	Similar mechanism as dorsal Barton's but with wrist in volar flexion at time of injury. Also referred to as *reverse Barton's fracture.* Much rarer than dorsal Barton's fracture.
Bennett's	Oblique fracture through base of the first metacarpal with dislocation of the radial portion of the articular surface.	Usually produced by direct force applied to the end of the metacarpal. Dorsal capsular structures disrupted by the dislocation. Marked tenderness along medial base of thumb.
Bosworth	Fracture-dislocation of the ankle resulting in the fibula being entrapped behind the tibia.	Rare injury, produced by a severe external rotation force applied to the foot. Physical examination reveals foot severely externally rotated in relation to the tibia.
Boxer's	Fracture of the neck of the fourth or fifth metacarpal.	Results from striking a clenched fist into an unyielding object, usually during an altercation, or against a wall, out of frustration or anger.
Chance's	Vertebral fracture, usually lumbar, involving the posterior spinous process, pedicles, and vertebral body.	Caused by simultaneous flexion and distraction forces on the spinal column, usually associated with use of lap seat belts. Anterior column fails in tension along with the middle and posterior columns. May be misdiagnosed as a compression fracture.
Chauffeur's	Solitary fracture of radial styloid.	Occurs from tension forces sustained during ulnar deviation and supination of the wrist. Name derives from occurrence in chauffeurs who suffered violent, direct blows to the radius incurred while turning the crank on a car, only to have it snap back, during previous eras.
Clay shoveler's	Fracture of the tip of the spinous process of the sixth or seventh cervical vertebra.	First described in Australian clay shovelers who sustained a fracture of the spinous process by traction as they lifted heavy loads of clay.
Colles'	Fracture of the distal radius with dorsal displacement and volar angulation, with or without an ulnar styloid fracture.	Most common wrist fracture in adults, especially in the elderly. Results from fall on an outstretched hand. Also known as *silver fork deformity,* which accurately describes the gross appearance in the lateral view. First described by Colles in 1814, before the advent of radiography.
Cotton's	Trimalleolar fracture.	Fracture of the lateral malleolus, fracture of the posterior malleolus, and either a fracture of the medial malleolus or a disruption of the deltoid ligament with visible widening of the mortise on ankle radiograph.
Dashboard fracture	Fracture of the posterior rim of the acetabulum.	Named for mechanism of injury: a seated passenger striking the knee on a dashboard, driving the head of the femur into the acetabulum.
Dupuytren's	Fracture-dislocation of the ankle.	Results from a similar mechanism as the better known Maisonneuve fracture (i.e., external rotation of the ankle), resulting in either deltoid ligament rupture or medial malleolus fracture, diastasis of the inferior tibiofibular joint, and indirect fracture of the fibular shaft. Maisonneuve was the student of Dupuytren.
Essex-Lopresti	Fracture of radial head with dislocation of distal radioulnar joint.	Results from longitudinal (axial) compression of the forearm.
Galeazzi's	Fracture of the shaft of the radius with dislocation of the distal radioulnar joint. Ligaments of inferior radioulnar joint are ruptured and head of ulna displaced from ulnar notch of the radius.	Results from fall on outstretched hand, with the wrist in extension and the forearm forcibly pronated. Inherently unstable with tendency to redisplace after reduction.
Hangman's	Fracture-dislocation of atlas and axis, specifically of pars interarticularis of C2 and disruption of C2-3 junction. Separation occurs between second and third vertebral bodies from anterior to posterior side.	Results from extreme hyperextension during abrupt deceleration. Most common cause is the forehead striking the windshield of a car during a collision. A bit of a misnomer in that hanging usually produces death by strangulation rather than cord damage.

Table 49-1 Common Fracture Names and Their Origins—cont'd

FRACTURE EPONYM OR NAME	DESCRIPTION	COMMENT
Hume's	Fracture of the proximal ulna associated with forward dislocation of the head of the radius.	Essentially high Monteggia's injury.
Jefferson's	Burst fracture of ring of C1, or atlas.	Axial loading results in a shattering of the ring of the atlas. Decompressive type of injury. Associated with disruption of transverse ligament; an unstable injury.
Jones	Transverse fracture of the metatarsal base, occurring at least 15 mm distal to the proximal end of the bone, distal to the insertion of the peroneus brevis.	Should not be confused with the more common avulsion fracture of fifth metatarsal styloid, produced by avulsion at the insertion of the peroneus brevis. Jones described the fracture that bears his name in 1902, after sustaining the injury himself while dancing.
Le Fort	Maxillary fracture.	Types I, II, and III (see Chapter 42).
Le Fort-Wagstaffe	Avulsion fracture of the anterior cortex of the lateral malleolus.	Rare pull-off injury of the fibular attachment of the anterior tibiofibular ligament.
Lisfranc's	Fracture located around the tarsometatarsal (Lisfranc's) joint, usually associated with dislocation of this joint.	Lisfranc, a field surgeon in Napoleon's army, described an amputation performed through the tarsometatarsal joint in a soldier who caught his foot in a stirrup when he fell off his horse. Since then, the joint has borne his name.
Maisonneuve	Fracture of proximal third of fibula associated with rupture of the deltoid ligament or fracture of the medial malleolus and disruption of the syndesmosis.	Results from external rotation of the ankle with transmission of forces through syndesmosis; proximally the force is relieved by fracture of the fibula. Described experimentally in 1840, before radiography.
Malgaigne's	Fracture of the ilium near the sacroiliac joint with displacement of the symphysis, or a dislocation of the sacroiliac joint with fracture of both ipsilateral pubic rami.	Resultant pelvic injury is unstable. Described by Malgaigne, based on clinical findings, in 1847.
March	Fatigue, or stress, fracture of the metatarsal.	Arises from long marches or other repetitive use trauma (e.g., marathon running) or less commonly from single stumbling movements.
Monteggia's	Fracture of the junction of the proximal and middle thirds of the ulna associated with anterior dislocation of the radial head.	Usually caused by fall on outstretched hand along with forced pronation of forearm or by a direct blow on the posterior aspect of the ulna. Reported by Monteggia in 1814.
Nightstick	Fracture of either ulna or radius, or both.	Name derived from a citizen's attempt to protect himself from a police officer's baton or "nightstick" by offering the forearm.
Piedmont	Closed fracture of the radius at the middle third–distal third junction, without associated ulnar fracture.	Named for a series of cases presented at the Piedmont Orthopaedic Society of Durham, North Carolina.
Pott's	Definitions vary (see comment); most commonly a bimalleolar fracture or a fracture of the distal fibula, 4-7 cm above the lateral malleolus.	The exact fracture Pott described in 1769 is uncertain; clearly it referred to a fracture of the lower fibula, usually associated with other fractures or dislocations about the ankle.
Rolando's	Intra-articular fracture at base of metacarpal. Frequently Y- or T-shaped, or may be severely comminuted.	Produced by an axial load with the metacarpal in partial flexion. Worse prognosis than a Bennett's fracture and, fortunately, rarer.
Salter-Harris	An epiphyseal fracture occurring in children or adolescents.	Graded I-V, depending on degree of involvement and/or displacement of epiphysis and metaphysis (see text dealing with Salter-Harris fractures and also Figure 46-1).
Smith's	Extra-articular fracture of the distal radius with volar displacement of distal fragment.	Reverse of the Colles' fracture but much more uncommon. Sometimes referred to as a "garden spade" deformity. Usually results from fall with force to back of hand. First described by Smith in 1847.
Stener	Avulsion of the ulnar corner of the base of the proximal phalanx of the thumb.	Bony equivalent of rupture of the ulnar collateral ligament, or "gamekeeper's thumb."
Teardrop	Wedge-shaped fracture of the anteroinferior portion of the vertebral body, displaced anteriorly.	Commonly involves a ligamentous injury and may produce neurologic injury.
Thurston Holland's fragment	Triangular metaphyseal fragment that accompanies the epiphysis in Salter-Harris type II fractures.	Described by Thurston Holland in 1929. The name is commonly hyphenated, although technically it should not be.
Tillaux	Isolated avulsion fracture of the anterolateral aspect of the distal tibial epiphysis.	Occurs in older adolescents (12-15 years) after the medial parts of the epiphyseal plates close but before the lateral part closes. External rotation force places stress on anterior talofibular ligament. Described by Tillaux in 1872.

www.ketabpezeshki.com 66485457-66963820

distal—and these thirds or the junction of any two of them (e.g., the junction of the middle and distal third of the tibia) are used to describe fractures. The most descriptive language possible should be used. It is better to say "closed fracture of the right ulnar styloid" than "closed fracture of the right distal ulna" because the former conveys more precise anatomic information.

An additional modifier describes the direction of the fracture line in relation to the long axis of the bone in question. A *transverse* fracture occurs at a right angle to the long axis of the bone (Fig. 49-1A), whereas an *oblique* fracture runs oblique to the long axis of the bone (Fig. 49-1B). A *spiral* fracture results from a rotational force and encircles the shaft of a long bone in a spiral fashion (Fig. 49-1C). A fracture with more than two fragments is termed *comminuted* (Fig. 49-1D).

The position and alignment of the fracture fragments (i.e., their relationship to one another) should be described. Fragments are described relative to their normal position, and any deviation from normal is termed *displacement.* By convention, the position of the distal fragment is described relative to the proximal one. Displacement may be described as a quantitative measurement (i.e., in millimeters) or as a percentage of the bone width. Figure 49-2 shows a dorsal displacement of the fractured radius, and Figure 49-3 shows lateral, or valgus, displacement of the distal tibia and fibula.

The terms *valgus* and *varus* are sometimes confusing. *Valgus* denotes a deformity in which the described part is angled away from the midline of the body. Conversely, *varus* denotes a deformity in which the angulation of the part is toward the midline. *Alignment* refers to the relationship of the longitudinal axis of one fragment to another; deviation from the normal alignment is termed *angulation.* The direction of angulation is determined by the direction of the apex of an angle formed by the two fracture fragments (Fig. 49-4). This angle is opposite to the direction of displacement of the distal fragment. The relative position or angulation of the distal fragment of a fracture may also be described with terms such as *radial* or *ulnar, dorsal* or *volar, anterior* or *posterior,* and *lateral* or *medial.* One should also be aware of rotational deformity, present when the distal fragment of a fracture is rotated to some degree along the axis of the bone itself. Especially in the digits of the hand, radial or ulnar deviation of a flexed finger can occur, and radiographs often underestimate the degree of clinical deformity and rotation present.

Descriptive Modifiers

A fracture is termed *complete* if it interrupts both cortices of the bone and *incomplete* if it involves only one. It should be noted whether a fracture extends into and involves an *articular surface.* Frequently the percentage of articular surface involved can only be estimated; in some cases the percentage that is actually involved dictates the need to perform a surgical reduction. In general, it is important that the articular surface be restored to anatomic integrity to prevent consequent traumatic arthropathy.

Avulsion fracture refers to a bone fragment that is pulled away from its normal position by either the forceful contraction of a muscle (Fig. 49-5A) or the resistance of a tendon or ligament to a force in the opposite direction (Fig. 49-5B). *Impaction* refers to the

forceful collapse of one fragment of bone into or onto another. In the proximal humerus, this collapse typically occurs in a telescoping manner, particularly in elderly patients, whose bones are soft and brittle. In the tibial plateau, impaction occurs frequently in the form of a depression (Fig. 49-6A and B), and in the vertebral bodies, impaction frequently occurs in the form of compression (Fig. 49-6C).

A fracture that occurs through abnormal bone is termed *pathologic*. A pathologic fracture is suggested whenever a fracture occurs from seemingly trivial trauma. Diseases that cause structural weakness predisposing to injury include primary or metastatic malignancies, cysts, enchondromata, and giant-cell tumors. In addition, osteomalacia, osteogenesis imperfecta, scurvy, rickets, and Paget's disease all weaken bones, making them susceptible to fracture. The term *pathologic* also is applied to fractures through osteoporotic bone when the demineralization is a result of disease, as in polio. Fractures through osteoporotic bone of the elderly usually are not described as pathologic. When fractures occur in normal bones and a history of "trivial trauma" is elicited, violence or battering should be suspected. Repeated low-intensity forces may lead to resorption of normal bone, resulting in a stress fracture. Other names for this condition are *fatigue fracture* and *march fracture* (see Table 49-1). Most stress fractures occur in the lower extremities and commonly affect individuals involved in activities such as running, basketball, aerobics, and dancing. Extrinsic factors such as training regimens, type of equipment used, and nutrition habits, as well as intrinsic factors such as anatomic variation, muscle endurance, and hormonal factors have all been associated with stress fractures. These injuries may not be recognizable on initial plain films; therefore management should be based on clinical diagnosis.[1] The tibia, fibula, metatarsals, navicular, cuneiform, calcaneus, femoral neck, or femoral shaft may be involved.[2,3]

Fracture Eponyms

Many fractures were described before the advent of radiography and are described by an eponym rather than the exact bony injury. These eponyms reflect the rich history of orthopedic care and, despite the objections of some, are still commonly used to describe orthopedic injuries (see Table 49-1).

Fracture Healing

Specific fractures are discussed in subsequent chapters. In general, the goal is to realign bony fragments so that healing or union can take place and normal function is restored. The process from fracture to union begins with a hematoma, caused by rupture of vessels crossing the fracture line. The hematoma bridges the fragments and is followed by an inflammatory phase when granulation tissue forms on the fracture surfaces. Resorption of the hematoma provides the first continuity between the fragments; however, this procallus provides no structural rigidity for bearing stress. With remodeling, callus subsequently is formed on the periosteal and endosteal surfaces of the bone, acting as a biologic splint. This area first becomes mineralized by deposition of calcium phosphate and then undergoes osseous metaplasia. Callus is resorbed as the original fracture surfaces develop firm bony union. In some bones, such as the skull and the neck of the femur, where periosteum is deficient, there may be virtually no callus formation.

Radiographic studies conducted 10 to 14 days after injury show the bone surrounding the fracture line becoming less dense because of localized bone resorption and hyperemia associated with the formation of granulation tissue. As a result, the fracture becomes considerably easier to visualize radiographically about 10 days after injury. After 2 to 3 weeks, soft tissue swelling has regressed, and callus first becomes visible, initially in a mottled pattern and then taking on a dense appearance. The callus undergoes organization, with peripheral margins becoming smooth as physically unstressed portions are resorbed.

In a healthy adult the whole process from injury to consolidation takes about 2 months for the humerus and about 4 months for a large bone such as the femur. Oblique fractures tend to heal more quickly than transverse fractures. Healing is quicker in children and slower in the elderly. The rate of fracture healing is affected by many factors, including the type of bone (cancellous bone heals faster than cortical bone); degree of fracture and opposition; and systemic states, such as hyperthyroidism or illness requiring ongoing cortiscosteroid treatment. Exercise speeds healing, whereas chronic hypoxia has been known to slow repair.

The presence of abundant callus seen on radiograph that is beginning to organize is usually associated with clinical union. If any suggestion of movement at the fracture site is noted on clinical examination, union is regarded as inadequate. Several terms are used to denote abnormal union. *Delayed union* is union that takes longer than usual for a particular fracture location. *Malunion* occurs when a residual deformity exists. *Nonunion* is the failure of a fracture to unite. When nonunion results in a false joint, it is termed a *pseudarthrosis.*

If the ends of the bone have remained constant on serial films and an adequate surrounding sheath of organizing callus can be seen, it is permissible for the patient to return to limited active use, even if the original fracture remains visible. The final process of consolidation develops later.

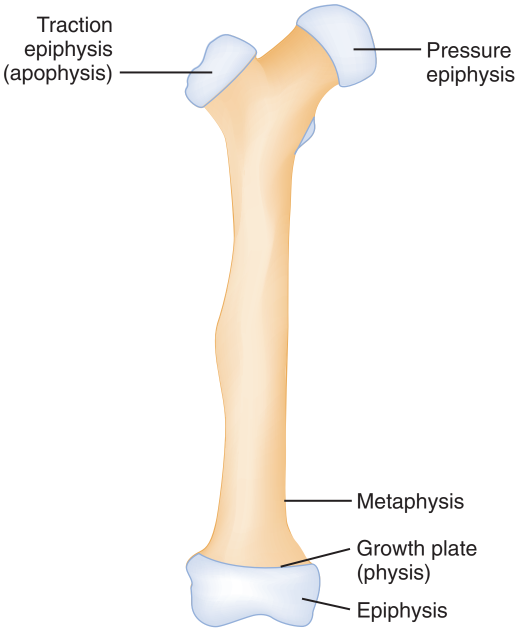

Figure 49-8. Anatomy of growing bone.

Fractures in Children

Certain features of children's bones distinguish pediatric fractures from adult fractures. Bones of children are necessarily soft and resilient and sustain numerous incomplete fractures. *Greenstick* fractures are incomplete angulated fractures of long bones. The resultant bowing of the bone causes an appearance resembling a moist, immature branch that breaks in a similar fashion when bent (Fig. 49-7A). A *torus* fracture is another form of incomplete fracture, characterized by a wrinkling or buckling of the cortex. In Greek architecture a torus is a bump at the base of a column, and these fractures, occurring at the end of long bones, take on such an appearance. These fractures may be extremely subtle on radiographs (Fig. 49-7B).

Another feature of growing long bones that is a frequent source of trouble and confusion is the presence of epiphyses, cartilaginous centers at or near the ends of bone that give rise to growth of the bone. Figure 49-8 is a schematic review of the anatomy of a growing bone. Because cartilage is radiolucent, the cartilaginous portion of an epiphysis is not visualized on radiographs. A tendency exists to consider only the ossified nucleus and to ignore the cartilaginous structure that bridges to the metaphysis. Cartilage is present even before an ossified nucleus is seen. Because the epiphyseal growth plate is represented by a radiolucent line, confusion may exist as to whether a fracture line is present. These complexities in interpreting radiographs in children sometimes, but not always, require comparison radiographic views of the uninjured side. Injuries to the epiphyses may result from either compressive or shearing forces. These injuries are relatively common during childhood as opposed to sprains or shaft fractures and should be considered in children with a "sprained

www.ketabpezeshki.com 66485457-66963820

Table 49-2 Salter-Harris Classification

	DESCRIPTION	DIAGRAM
Type I	Fracture extends through the epiphyseal plate, resulting in displacement of the epiphysis (this may appear merely as widening of the radiolucent area representing the growth plate).	Type II	As above; in addition, a triangular segment of metaphysis is fractured.	Type III	Fracture line runs from the joint surface through epiphyseal plate and epiphysis.	Type IV	Fracture line occurs as in type III but also passes through adjacent metaphysis.	Type V	This is a crush injury of the epiphysis; it may be difficult to determine by radiographic examination.	
ankle" because of the relative weakness of the cartilaginous growth zone, which separates before stronger ligaments and bones are torn or broken. Epiphyseal injuries should be described according to the Salter-Harris classification (Table 49-2).

Type I injuries involve only a slip of the zone of provisional calcification. Comparison radiographs are usually necessary to detect small slips. Swelling and tenderness over an epiphysis (e.g., of the lateral ankle) and a negative radiograph suggest an epiphyseal injury rather than a sprain, because the epiphysis is weaker than the overlying ligaments.

Type II injuries are similar to type I injuries, with a fracture extending into the metaphysis. The triangular metaphyseal fragment sometimes is referred to as the *Thurston Holland sign* (see Table 49-1). Type II injuries account for approximately three fourths of all epiphyseal fractures. Because the germinal layer is not involved, growth disturbance usually does not occur with type I and II injuries. These injuries are amenable to closed reduction and immobilization without internal fixation.

Type III injuries are composed of a slip of the growth plate plus a fracture through the epiphysis, involving the articular surface. Because this fracture involves the germinal layer, growth may be disrupted. Anatomic reduction does not eliminate the possibility of growth disturbance. Type IV fractures are similar to type III fractures, with the additional involvement of a metaphyseal fracture. Open reduction and internal fixation are usually required to obtain anatomic alignment of the physis and articular surface. Growth disturbance occurs in a high proportion of patients.

Type V fractures are crush injuries of the epiphyseal plate, usually produced by a compressive force.[3] This type of injury usually occurs in joints that move in one plane, most commonly the knee and ankle. Because this injury occurs in a radiolucent area, the injury may be difficult to diagnose on radiograph, but it is suggested by mechanism of injury and pain over the epiphysis. The diagnosis can be established by MRI if hemorrhage or a hematoma is identified within the growth plate immediately after injury.[3-5] Also reported is loss of MRI signal from the cartilage.[6] Rarely are type V injuries diagnosed acutely, and growth arrest manifested by shortening or angulation is the rule with this injury.

Physeal injuries occur twice as often in boys as in girls and are most common in boys aged 12 to 15 years and in girls aged 9 to 12 years.[7] Distal physes are injured more often than proximal physes, and the most common anatomic locations include the distal radius, phalanges, and distal tibia. Distal radius fractures account for two thirds of fractures in pediatric patients in the ED.[8] The incidence of these fractures has increased by 40% over the past three decades, possibly because of a change in recreational activities, such as increased skiing and skating among boys and increased basketball, soccer, and skating among girls.[9] Most distal radius type I and II fractures can be treated through closed reduction, though this may be more technically difficult with completely displaced both-bone fractures. Similar practice has been applied to distal tibia type I and II fractures, though the incidence of premature physeal closure was shown to be 3.5 times higher if the residual fracture displacement was greater than 3 mm in postreduction radiographs.[10] Growth arrest as a complication of physeal fracture is most likely to be seen at the distal femur, distal and proximal tibia, and distal radius.[7]

Diagnostic Modalities for Fracture Diagnosis

Plain Radiography

Conventional radiography is the mainstay in diagnosing fractures. In addition to confirming or excluding fractures, it can identify other pathologic conditions. With penetrating trauma, foreign bodies, air, and gas also may be detected. With minor trauma and when good follow-up monitoring is ensured, it is acceptable to delay radiography. Delay cannot be permitted, however, when the suggested injury is one that might be made worse by delayed diagnosis, such as a nondisplaced hip fracture.

Biplanar radiographs of an injured extremity should be obtained to fully delineate the bony injury. Conventional radiographic evaluation of long bones include at least two orthogonal views, and an oblique view is also usually obtained. In certain locations, such as the phalanges, oblique views are necessary. If doubt still exists, the clinician should ask for more views in various degrees of obliquity to the other films. A fracture line is most visible when it is parallel to the x-ray beam and is invisible when it is exactly 90 degrees to the beam. *The clinician should never accept a study that examines the bone in only one plane.* When a long bone is found to be fractured, it is imperative that the bone be viewed radiographically in its entire length.

Each film is examined to ensure that proper technique has been used and that no important area is omitted from the film. Overexposed films may fail to reveal an abnormality. Although some fine detail is lost on portable films, these are acceptable in unstable patients, in whom the risk of moving the patient does not outweigh the benefit of the more detailed study. Even with good technique, some fractures are not visible initially and do not appear until the margins of the fracture absorb. Absorption widens the radiolucent line, and a defect appears in 7 to 10 days. At that time, new bone produced beneath the periosteum at the margins of the fracture accentuates the fracture. Accordingly, if a fracture is suggested but not visible at the initial visit, the injury should be treated as a fracture and reexamined clinically and radiographically in 7 to 10 days, and the patient should be informed of the rationale for this regimen.

Stress views of joints are used in some instances to evaluate the degree of ligamentous injury. Some authors argue against the use of stress views, citing a risk of further injuring an already traumatized structure, additional radiation exposure to the patient and

www.ketabpezeshki.com 66485457-66963820

the technologist, and the possibility that pain may not allow sufficient stress to be applied. For these reasons, stress views should be used judiciously in circumstances when other methods of evaluating ligamentous injuries are not available. *Comparison views* are useful in selected situations but should not routinely be performed in all pediatric examinations.[11] If a fracture is definitely present on the affected side, the comparison view exposes the child to radiation and adds expense with no benefit. Similarly, an experienced physician generally is able to read a normal film with reasonable certainty. It is reasonable to use comparison views in instances when radiographs are inconclusive and when the confusion arises specifically out of the need to distinguish between a possible fracture and normal developmental anatomy. Obtaining a wide field of the affected extremity is more useful than routine comparison views for a young child because the child often does not localize the pain well; this is especially true with regard to complaints of knee pain in cases of hip injury or wrist complaints in forearm and elbow injury. Comparison views sometimes are helpful in adults when a question of accessory ossicles or nonfused bones (e.g., bipartite patella) exists because these anomalies are usually bilateral. The bleeding that inevitably accompanies fractures may produce soft tissue swelling, which may impinge on or obliterate overlying muscle planes. Fat pads, such as in the elbow, may be displaced. Another useful sign is the fat-fluid level, which may accompany fractures extending into the knee joint. The fat-fluid level is visible, however, only if the cross-table technique is used.

The bones themselves should be examined systematically. Normal adult bones possess a smooth unbroken contour. A distinct angle is highly suggestive of a fracture. In an adult the typical fracture is represented by a lucent line that interrupts the smooth contour and usually extends to the opposite side. Nutrient arteries may be confused with fractures but have different radiographic characteristics: They are fine, are sharply marginated, extend obliquely through the cortex, and are less radiolucent than fractures. *Pseudofractures* can be created by soft tissue folds, bandages or other overlying material, or a radiographic artifact called the *Mach effect*. If lucencies extend beyond the bones, the line is highly unlikely to represent a fracture. Anomalous bones and calcified soft tissue likewise may be mistaken for fractures. Avulsions and small fracture fragments have an irregular surface that lacks well-corticated margins and a defect in the adjacent bone is present, whereas anomalous ossification centers (accessory ossicles) and sesamoids are characterized by smooth cortical margins. Reference texts are useful in identifying and confirming these anomalies because they tend to occur in predictable locations.[12] Compression fractures are represented by increased density rather than a lucency. Finally, the most commonly missed fracture is the second fracture. One should be diligent in searching for additional fractures after discovering the first fracture on a study. In particular, certain paired fractures, such as the distal tibia and proximal fibula, should be sought out.

Special Imaging Techniques

Radionuclide Bone Scanning. In the past, radionuclide bone scanning was used to detect skeletal abnormalities not radiographically evident in children and adults.[13] Occult lesions, especially stress fractures, acute osteomyelitis, and tumors, can be detected on these scans, although there are problems with specificity and sensitivity. This modality has been largely supplanted by CT and MRI and now is seldom used.

Computed Tomography. Computed (digital) radiography is now in widespread use. Although conventional radiography remains the initial imaging study of choice for skeletal trauma, CT offers a more detailed and diagnostically sensitive evaluation of bones and joints. With improved resolution and speed, multidetector-row CT captures large volumetric data sets from which two- and three-dimensional images can be created.[14,15] Workstation post-processing has become an integral part of the examination. Two-dimensional multiplanar reconstruction in any chosen plane, and three-dimensional surface rendering techniques provide images with unprecedented quality, even in the presence of metallic implants or fixation devices.[16]

CT is used to confirm possible fractures or to better define displacement, alignment, or fragmentation of fractures. It is also useful in trauma to rule out cervical spine fracture when plain films are equivocal and in noncompressive vertebral fractures to assess the number of fragments and their spatial relationship to the spinal canal. CT is used frequently to define the integrity of articular surfaces in the acetabulum, knee, wrist, or ankle and in Salter-Harris type IV fractures.[4] In the multiple trauma patient requiring thoracic, abdominal, and pelvic CT imaging to rule out visceral injury, the soft tissue protocols may be adapted to acquire diagnostic bone images, as well.[17] During imaging of the chest, abdomen, or pelvis, data sets are created from which the thoracolumbar spine and bony pelvis can be derived.

Magnetic Resonance Imaging. MRI constitutes the most advanced noninvasive examination of orthopedic structures, delineating lesions of bone, cartilage, ligaments, and other structures, such as menisci, disks, and epiphyseal structures. MRI is expensive and time-consuming and should be reserved for instances in which the diagnosis is in doubt and specific findings would alter the treatment.

Ultrasound Imaging. Point-of-care ultrasound may be an effective tool for the diagnosis of fractures when conventional radiography is unavailable. Through use of bedside ultrasonography, fractures are visualized as an interruption of the linear bony cortex and may be clinically correlated during the physical examination of the affected area. Ultrasound can be effective in the diagnosis of long bone fractures, orbital floor fractures, rib fractures, and occult fractures of the foot and ankle.[18] Ultrasound can be used in "real-time" during fracture reduction to confirm proper reduction and alignment of bony fragments.[19]

Complications of Fractures

Infection (Osteomyelitis)

Any fracture communicating with the surface of the skin is termed an *open fracture*. Open fractures are treated as true orthopedic emergencies because of the risk of infection; the dreadful nature of the complication of osteomyelitis dictates that no time should be wasted in initiating therapy (Box 49-2). Wounds should be irrigated of gross debris and covered with a sterile dressing, and parenteral antibiotics should be instituted as early as possible.[20]

Currently, suggested therapy includes a first-generation cephalosporin, such as cefazolin, for all open fractures, with the addition of an aminoglycoside for grade II or III fractures.[21,22] Early versus delayed treatment of open fractures and its subsequent effect on rates of infection has been a source of debate. Historic guidelines recommending débridement of open fracture wounds within 6 hours of injury were based on animal experiments conducted in the 1890s.[23] Current human studies suggest no clear advantage to performing surgical débridement within 6 hours of injury. The timing of débridement—less than 6 hours versus more than 6 hours after injury—had no effect on clinical or functional outcome in a prospective multicenter study of severe lower-extremity fractures.[24] Other retrospective studies and literature reviews advocate early débridement and irrigation of the wound within the first 24 hours of injury to prevent infection.

Certain open fractures of the finger present a notable exception to the previous recommendation. Such injuries, especially an open distal tuft fracture, are common when the phalanx of a finger is

www.ketabpezeshki.com 66485457-66963820

subject to crush injury (e.g., by a door) and there exists a skin defect overlying a fractured bone. In a prospective randomized, placebo-controlled study of 193 patients with open fracture of the finger, flucloxacillin or placebo was administered to randomized patients with open phalangeal fractures, and both groups were treated with aggressive surgical irrigation and débridement. No significant difference was found in the infection rate between the groups, and no patient developed osteomyelitis. The data suggest that vigorous irrigation and débridement are adequate primary treatment for open phalangeal fractures in fingers with intact digital arteries.[25] Such injuries might be repaired by the emergency physician without consultation.

Hemorrhage

Because of the rich blood supply to the skeleton, fractures can result in large amounts of blood loss, shock, and death from exsanguination. In particular, certain pelvic fractures can cause great blood loss as adequate tamponade is not possible. In adults, blood loss can range from 100 mL from a forearm fracture to 3 L from a pelvic fracture (Table 49-3).

Vascular Injuries

Vascular injuries characteristically are associated with certain fractures and may be limb-threatening. Fractures and dislocations (at the femorotibial articulation) of the knee result from tremendous force that often injures the popliteal artery. Fracture of the femoral neck requires emergent reduction and fixation to protect the blood supply to the femoral head.[23] In the extremities, assessment of vascular injuries may be difficult. The initial survey should note the presence or absence of pulses and the state of capillary filling. If an end artery is completely disrupted, the tissue distal to the injury may exhibit the classic five *P*s: pain, pallor, pulselessness, paresthesias, and paralysis. Incomplete and subclinical injuries occasionally occur that initially may be asymptomatic and undetectable. Likewise, in an unconscious, multiply injured patient, major vascular injuries may not be obvious. The mechanism of injury and anatomy dictate the need to assess the possibility of an injured vessel. If pulses cannot be palpated, a Doppler stethoscope should be used to listen for blood flow. Even palpable pulses may be misleading, however, because it has been shown that in 10 to 20% of significant arterial injuries, distal pulses may initially be normal. When pulses are present but the mechanism of injury suggests the possibility of vascular injury, additional diagnostic studies or surgical exploration may be necessary. If a limb is clearly not perfused, operative vascular exploration and repair should take place promptly. Late complications of undiagnosed vascular injuries include thrombosis, arteriovenous fistulae, aneurysm, false aneurysm, and tissue ischemia with limb dysfunction. Delay of vascular injury repair is a risk factor for consequent amputation.[26]

Traditionally, conventional arteriography has been the diagnostic modality of choice in evaluating vascular injuries; however, it is invasive and costly. Alternative methods of vascular assessment include arterial pressure indices and serial physical examinations. Recent advances in computed tomographic angiography have proven it an effective alternative to conventional arteriography, and its advantages include immediate availability and noninvasiveness.[27]

Nerve Injuries

Nerves can be injured by either blunt or penetrating trauma. *Neurapraxia* is the contusion of a nerve, with disruption of the ability to transmit impulses. Paralysis, if present, is transient, and sensory loss is slight. Normal function usually returns to a neurapraxic nerve in weeks to months. *Axonotmesis* is a more severe crush injury to a nerve. The injury to nerve fibers occurs within their sheaths. Because the Schwann tubes remain in continuity, spontaneous healing is possible but slow. *Neurotmesis* is the severing of a nerve, usually requiring surgical repair. Age, site, injured nerve, and delay between injury and repair have all been shown to influence prognosis after microsurgical repair.[28] Because of proximity, specific nerve injuries characteristically accompany certain fractures (Table 49-4). For example, in the upper extremity,

Box 49-2 Classification and Emergency Management of Open Fractures

Grades

Grade I: Wound less than 1 cm long, punctured from below
Grade II: Laceration 5 cm long; no contamination or crush; no excessive soft tissue loss, flaps, or avulsion
Grade III: Large laceration, associated contamination or crush; frequently includes a segmental fracture
- IIIA: Involves extensive soft tissue stripping of bone
- IIIB: Periosteal stripping has occurred
- IIC: Major vascular injury present

Management

1. Control hemorrhage in field with sterile pressure dressing after carefully removing gross debris (e.g., wood, clothing, leaves).
2. Splint without reduction, unless vascular compromise is present.
3. Irrigate with saline and cover with saline-soaked sponges after arrival in the emergency department.
4. Begin intravenous antibiotic prophylaxis, usually a first-generation cephalosporin for grade I, with the addition of an aminoglycoside for grades II and III.
5. Administer tetanus prophylaxis, including tetanus immune globulin, for large crush wounds.

Table 49-3 Blood Loss Associated with Fracture in Adults

FRACTURE SITE	AMOUNT OF BLOOD LOSS (mL)
Radius and ulna	150-250
Humerus	250
Tibia and fibula	500

Table 49-5 Life-Threatening or Limb-Threatening Emergencies

CONDITION	POSSIBLE ADVERSE OUTCOME
Open fracture	Osteomyelitis
Fracture or dislocation with major vascular disruption (especially popliteal)	Amputation
Major pelvic fracture	Exsanguination
Hip dislocation	Avascular necrosis of femoral head
Compartment syndrome	Ischemic contracture; myoglobinuria, renal failure

a distal radius fracture caused by a high-energy insult can be associated with acute dysfunction of the median nerve. Deteriorating neurologic function may necessitate temporary or definitive stabilization of a fracture.

When the nerve is completely severed, all functions are absent, including superficial sensation to touch, pain, and temperature; deep sensation to muscle and joint movements, position, deep pressure, and vibration; motor supply and deep tendon reflexes (to distally innervated muscle groups); and response to electrical stimulation. For less severe injuries, any subjective change in sensation should be noted. Light touch is a good screening test. Two-point discrimination is a more sensitive examination and should be used routinely in evaluating digital nerves. Separating the ends of a paper clip a few millimeters apart and asking the patient to discriminate between one or two points may easily accomplish this. The discrimination on the injured digit is then compared with the uninjured ones. Two-point discrimination may be of limited value in children in whom a subjective response may be misleading; this is also true in patients with calloused fingertips and in patients who are uncooperative, comatose, in severe pain, or intoxicated. Testing for sympathetic nerve function with the O'Riain wrinkle test may be helpful.[29,30] Soaking the normally innervated digits in warm saline for 20 minutes causes the digital pulps to wrinkle through a mechanism that is not understood. The presence of wrinkling probably indicates the nerve is intact, whereas absence of wrinkling may be more difficult to interpret. The Ninhydrin test, another sudomotor test used to assess peripheral nerve integrity, is reportedly more reliable than the O'Riain test but is not practical to perform in the ED.

Compartment Syndrome

Compartment syndrome is a serious acute emergency complication that should be considered whenever pain and paresthesias occur in an extremity after a fracture within an enclosed osseofascial space (Table 49-5). The immediate threat is to the viability of nerve and muscle tissue within the involved compartment, but infection, gangrene, myoglobinuria, and renal failure also may ensue. Compartment syndrome is associated most commonly with a closed long bone fracture of the tibia, but it also is well described in the thigh, forearm, arm, hand, and foot.[31-35] In addition, compartment syndrome can occur with soft tissue trauma alone and even with open fractures. It also has been described in a host of unusual situations, including prolonged procedures in the lithotomy position, the tuck position (knees tucked to the chest for lumbar surgery), coma, spontaneous hemorrhage, intravenous injections, and the application of excessive traction in treatment of a fracture.[36,37] Acute surgical stabilization of a fracture is also associated with higher rates of compartment syndrome in the postoperative period.[38]

Pathophysiology. Increased pressure in a closed nonexpandable compartment essentially represents a mismatch between the volume of that space and its contents. As such, it may arise from one of three circumstances: (1) increased compartment contents, (2) decreased compartment volume, or (3) external pressure (Box 49-3). As tissue pressure increases, so does venous pressure, resulting in compromise of the local circulation and tissue hypoxia; this is believed to occur at pressures that are above normal diastolic pressure but below systemic arterial pressure because of a reduced arteriovenous gradient at the tissue level. The body responds by releasing histamine in an attempt to dilate capillaries and increase blood flow to the affected area. Histamine also increases capillary membrane permeability, resulting in a leak of proteins and fluid into the surrounding tissue, further increasing compartment pressure.

Box 49-3 Causes of Compartment Syndrome

Increased Compartment Content

- Bleeding
  - Major vascular injury
  - Coagulation disorder
  - Anticoagulant therapy
- Increased capillary filtration
  - Reperfusion after ischemia
    - Arterial bypass grafting
    - Embolectomy
    - Ergotamine ingestion
    - Cardiac catheterization
    - Lying on limb
  - Trauma
    - Fracture
    - Convulsion
  - Intensive use of muscle
    - Exercise
    - Seizures
    - Eclampsia
    - Tetany
  - Burns
    - Thermal
    - Electrical
  - Intra-arterial drug injection
  - Orthopedic surgery
    - Tibial osteotomy
    - Hauser's procedure
    - Reduction and internal fixation of fractures
  - Snakebite
- Increased capillary pressure
  - Intensive use of muscles
  - Venous obstruction
    - Phlegmasia cerulea dolens (i.e., acute inflammation and edema of the legs)
    - Ill-fitting leg brace
    - Venous ligation
  - Diminished serum osmolarity (i.e., nephrotic syndrome)

Decreased Compartment Volume

- Closure of fascial defects
- Excessive traction on fractured limbs

Miscellaneous

- Infiltrated infusion
- Pressure transfusion
- Leaky dialysis cannula
- Muscle hypertrophy
- Popliteal cyst

External Pressure

- Tight casts, dressings, or air splints
- Lying on limb

From Matsen FA III: Compartmental Syndromes. New York, Grune & Stratton, 1980.

www.ketabpezeshki.com 66485457-66963820

As tissue pressure continues to increase, venous blood flow is impaired as capillary perfusion pressure is exceeded. Finally, arterial capillary blood flow falls to a point at which the basic metabolic needs are no longer met, leading to ischemic necrosis of muscles and nerves within the compartment. An important concept in the management of compartment syndrome is that because local venous pressure cannot be significantly below local tissue pressure, and because elevation of a dependent limb decreases local arterial pressure by 0.8 mm Hg for each 1 cm of limb elevation, elevation of a limb with resultant reduction in the local arteriovenous gradient may be counterproductive and may exacerbate compartment syndrome. Vascular spasm seems to play an insignificant or minimal role in the development of compartment syndrome, as evidenced angiographically, where spasm has never been shown, and clinically, where it is observed that distal pulses usually are maintained until late in the course.

Normal compartment pressure is 0 mm Hg. Microcirculation generally is impaired when tissue pressures reach 30 mm Hg or more; however, some patients can tolerate much higher compartment pressures without development of compartment syndrome. Controversy exists over attempts to define compartment syndromes on the basis of specific tissue pressure. The tolerance to tissue ischemia varies among individuals because of shock, compensatory hypertension, altered tone in resistance vessels, preexisting vascular disease, and other unknown factors. Inadequate perfusion and relative ischemia begin when tissue pressure within a closed compartment increases to within 20 mm Hg of a patient's diastolic pressure or, more accurately, within 30 mm Hg of the mean arterial pressure.[39] When tissue pressure equals or exceeds the patient's diastolic pressure, tissue perfusion effectively ceases. The development of muscle ischemia depends not only on the magnitude but also on the duration of elevated pressure. Intracompartmental pressures do not measure muscle and nerve ischemia but rather suggest the existence of the proper setting for compartment syndrome.

Anatomic Considerations and Risk Factors. Compartment syndrome theoretically can develop in any location where neuromuscular tissue is contained in a limiting envelope. The condition has been reported in the leg, thigh, buttock, arm, forearm, and hand (Box 49-4). By virtue of its location and higher likelihood of sustaining high-energy trauma, the leg, particularly the anterior compartment, is most commonly involved. Higher rates of compartment syndrome are seen with open fractures than with closed fractures, despite the fascial rents that accompany open fractures. The higher energy of injury observed with open fractures, with resultant tissue trauma, swelling, and bleeding, may account for this observation.

In a study of 164 patients treated over an 8-year period in the United Kingdom, a fracture was present in 69%, and half of these involved the tibial shaft.[31] Perhaps more significant is that 31% of patients had only soft tissue injury *without* fracture. Most patients were men younger than age 35. Ten percent of patients either had a bleeding disorder or were taking anticoagulants. Traffic accidents and sports activities were the most common mechanisms of injury.

Clinical Presentation. Compartment syndrome is a clinical diagnosis. In a conscious and fully oriented patient, pain that is disproportionate to the injury or physical findings is a hallmark finding in compartment syndrome. Pain often is characterized as deep, burning, and unrelenting and is difficult to localize. The need for increasing amounts of analgesics should not lead the clinician automatically to the conclusion that the patient is drug-seeking; rather, it should serve as a prompt to the possibility that a compartment syndrome is developing or is present.

Pain on passive stretching of the muscle groups in the suggestive compartment is an important finding. In addition, active flexion of involved muscles may produce pain. Other reliable suggestive signs and symptoms are hypoesthesias and paresthesias in the distribution of nerves crossing the compartment or tenderness, tenseness, or the sensation of tightness of the compartment.

Skin color, temperature, capillary refill, and distal pulses all are unreliable monitors for compartment syndrome because the pressure necessary to produce compartment syndrome is well below arterial pressure. Pallor and loss of pulses are late and ominous signs. Diminished pulses should suggest concomitant pathologic conditions responsible for reduced arterial flow. Although it is still frequently taught that the five *P*s (pain, pallor, pulselessness, paresthesias, and paralysis) are signs and symptoms of compartment syndrome, this is generally not true. Rather, they are the signs of acute disruption of arterial flow. Subjective complaints are an important indicator of compartment syndrome. Patients who are not fully alert or cooperative are assessed with particular care.

Diagnostic Tests. If the history and examination suggest compartment syndrome, compartment pressures should be measured with any of the commercially available monitors (Fig. 49-9).[40,41] The two most common methods of determining compartment pressures are the slit-catheter techniques and the side-port needle. The Stryker Intra-Compartmental Pressure Monitor system is a hand-held digital device that is easy to use with minimal training. Care should be taken to zero the monitor in on the plane in which it will be inserted to account for the effects of gravity. It is also paramount that the appropriate compartment be measured. Pressures of less than 30 mm Hg generally do not produce compartment syndrome. Pressures exceeding 30 mm Hg or within 30 mm Hg of the patient's mean arterial pressure are an indication for fasciotomy. Serial or continuous pressure measurements should be performed in cases that are not clear-cut. A rising or sustained elevated compartment pressure is superior to a single measurement as an indicator of acute compartment syndrome or the need for fasciotomy. Compartment syndrome can occur at pressures significantly below systemic pressure. Doppler ultrasound is not useful in evaluating these patients because excellent arterial blood flow may be documented even in the presence of a significant compartment syndrome. Newer devices based on near-infrared spectroscopy (NIRS) measurement of tissue oxygenation have proven effective experimentally in detecting compartment syndrome but will require validation in the clinical setting before widespread application.[42,43]

Treatment, Complications, and Disposition. Complete fasciotomy is the only treatment that can reliably normalize elevated compartment pressure. Preparation for surgery is done as quickly as possible. Delaying fasciotomy for more than 12 hours often results in irreversible myonecrosis and nerve damage. While the patient is awaiting definitive treatment, the affected part should *not* be elevated above the level of the heart because this maneuver does not improve venous outflow and reduces arterial inflow. Slight dependency has been suggested to maximize the pressure head in the extremity.

Because tissue compartments are more pliable soon after injury, the rate of extremity swelling is greater in the immediate postinjury period, and tends to peak at 36 to 48 hours after injury.[44] Extremity swelling decreases over a similar duration. Rhabdomyolysis, hyperkalemia, and myoglobinuria may occur and should be managed aggressively to avoid renal failure. Lactic acid also is released from necrotic muscle tissue. Other complications include infection and tissue loss.

Delayed treatment results in loss of nerve and muscle function and eventual contracture formation. The magnitude of these disasters may be measured by the fact that in 2004, the average indemnity award in cases of missed compartment syndrome was nearly $426,000. Awards were proportional to the delay beyond 8 hours in performing fasciotomy and the number of the five *P*s indicating ischemia that were present during the initial missed diagnosis.[45] For these reasons, when the diagnosis of compartment syndrome is confirmed, fasciotomy should be done without delay.

Avascular Necrosis

Because of their blood supply, certain bones may undergo avascular necrosis after fracture, especially if fractures are comminuted and go untreated for any length of time. The femoral head, talus, scaphoid, lunate, and capitate are particularly prone to this complication.[46-49] These injuries are described in subsequent chapters.

Complex Regional Pain Syndromes (Reflex Sympathetic Dystrophy and Causalgia)

Definitions. The terms *reflex sympathetic dystrophy* (RSD) and *causalgia* have been used to describe pain syndromes that sometimes follow fractures, orthopedic surgery, soft tissue injuries, and other unrecognized trauma to the limbs and their appendages. Other names previously used for this spectrum of post-traumatic injuries include *Sudeck's atrophy, shoulder-hand syndrome,* and *postinfarction sclerodactyly.* In an attempt to reduce misunderstanding about their etiology and treatment, the International Association for the Study of Pain (IASP) issued a consensus statement renaming the syndromes formerly called *reflex sympathetic dystrophy* and *causalgia.*[50,51] *Complex regional pain syndrome type 1* (CRPS-1), replacing the term *reflex sympathetic dystrophy,* is a pain syndrome that develops after an initiating noxious event, extends beyond the distribution of a single peripheral nerve, and is usually disproportionate to the inciting event. The site is most often the distal end of the affected extremity, with a distal-to-proximal gradient. It is associated with edema, changes in blood flow to the skin, abnormal sudomotor activity in the region of the pain, allodynia (pain resulting from non-noxious stimulation to the skin), hyperpathia (pain persisting or increasing after mild or light pressure), or hyperalgesia. The presence of a condition that otherwise would explain the degree of pain and dysfunction excludes the diagnosis of CRPS-1. Because so much of the literature still refers to RSD, this chapter still uses the terms *RSD* and *CRPS-1* interchangeably. The definition of *CRPS-2* is the same as for CRPS-1 except that there is demonstrable peripheral nerve injury. This term replaces *causalgia* under the IASP taxonomy.

Pathogenesis and Etiology. The pathogenesis of CRPS-1 has not been elucidated. Current research suggests that central and peripheral sensitization after a noxious event, inflammation, alteration of sympathetic and catecholaminergic function, altered limb representation in the somatosensory cortex, genetic factors, and psychophysiologic interactions may all play a role.[52] Cases of CRPS-1 have been reported after fractures and as iatrogenic complications of surgery or after minor procedures, including subcutaneous excision and intravenous injection. Forceful manipulations and tight casts also are alleged to have produced the syndrome. In 10 to 26% of patients, no inciting event is identified.[53,54]

Although malingering and secondary gain are suspected in some patients, they are not the causes in most patients, as evidenced by pathologic tissue changes in patients who actually have CRPS-1.[55] CRPS-1 occurs in children and adolescents.[56] Girls are affected three times as often as boys, and the median age is 12 years. The lower limb is affected twice as often as the upper, and history of inciting trauma can be identified in only half the children with the disorder.

Diagnosis. No correlation exists between the severity of the original trauma and the incidence, severity, and cause of the symptoms, making early diagnosis a challenge, especially after trivial injury. Early diagnosis is crucial because the earlier treatment is initiated, the better the response. Although consensus-based diagnostic criteria were proposed by the IASP in 1994, because of their low specificity, there is no agreement on the best method for diagnosis of CRPS, and several sets of diagnostic criteria exist.[57] Bruehl's and Veldman's criteria sought to improve the IASP criteria, but there is no reason to recommend one set of criteria over another (Table 49-6).[57]

Treatment. Treatment of CRPS is controversial. Debate arises because published randomized controlled trials provide limited evidence to formulate treatment recommendations; individual response to treatment varies; and experts disagree regarding the pathogenesis of the disease. A multidisciplinary approach, including physical therapy and psychological counseling, is often necessary for treatment of CRPS.[58] For some patients, definitive

www.ketabpezeshki.com 66485457-66963820

Table 49-6 Diagnostic Criteria for Complex Regional Pain Syndrome (CRPS) Type 1*

NAME	CRITERIA
IASP 1994 consensus criteria	Criteria 2, 3 and 4 are necessary for a diagnosis of CRPS type 1. 1. Type I is a syndrome that develops after an initiating noxious event. 2. Spontaneous occurrence of pain in the absence of an external stimulus, allodynia (pain caused by a mechanical or thermal stimulus that normally does not provoke pain), or hyperalgesia (exaggerated response to a stimulus that is normally painful) that is not limited to the territory of a single peripheral nerve and is disproportionate to the inciting event. 3. There is or has been evidence of edema, skin blood flow abnormality, or abnormal sudomotor activity (sweating) in the region of the pain since the inciting event. 4. This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.
Bruehl's criteria: IASP-family	1. Continuing pain disproportionate to any inciting event. 2. Patient must report at least one symptom in each of the following categories: a. Sensory: reports of hyperesthesia b. Vasomotor: reports of temperature asymmetry or skin color changes or skin color asymmetry c. Sudomotor or edema: reports of edema or sweating changes or sweating asymmetry d. Motor or trophic: reports of decreased range of motion or motor dysfunction (weakness, tremor, dystonia) or trophic changes (hair, nail, skin) 3. Must display at least one sign in two or more of the following categories: e. Sensory: evidence of hyperalgesia (to pinprick) or allodynia (to light touch) f. Vasomotor: evidence of temperature asymmetry or skin color changes or asymmetry g. Sudomotor or edema: evidence of edema or sweating changes or sweating asymmetry h. Motor or trophic: evidence of decreased range of motion or motor dysfunction (weakness, tremor, dystonia) or trophic changes (hair, nail, skin)
Veldman's criteria	1. Presence of four out of five symptoms: a. Diffuse pain during exercise b. Temperature difference between affected and unaffected extremity c. Color differences between affected and unaffected extremity d. Volume differences between affected and unaffected extremity e. Limitations in active range of movement of the affected extremity 2. Occurrence or increase of symptoms during or after use. 3. Symptoms in an area larger than the area of the primary injury.

From Quisel A, Gill JM, Witherell P: Complex regional pain syndrome underdiagnosed. J Fam Pract 54:524-532, 2005.
IASP, International Association for the Study of Pain.
*IASP definition of CRPS-1: A variety of painful conditions following injury that appear regionally, having a distal predominance of abnormal findings, exceeding in both magnitude and duration the expected clinical course of the inciting event and often resulting in significant impairment of motor function, and showing variable progression over time. (All three criteria sets use this definition).

treatment involves sympathetic blockade, usually with regional anesthesia and occasionally by surgical sympathectomy. Oral medications, including bisphosphonates, calcitonin, indomethacin, corticosteroids, tricyclic antidepressants, gabapentin, acupuncture, spinal cord stimulation, regional nerve blocks, and other medications and methods, have been used to treat RSD with variable success.[59,60] In one study, vitamin C was shown to reduce the incidence of RSD after wrist fracture.[61]

Fat Embolism Syndrome

Fat embolism refers to the presence of fat globules in the lung parenchyma and peripheral circulation after a long bone fracture or major trauma.[62] The phenomenon of fat embolization is probably common as a subclinical event after long bone fracture. Intravascular fat droplets appear in nearly one of five patients admitted with major trauma, although not all patients are symptomatic or require treatment.

Fat embolism syndrome is a serious manifestation of fat embolism, occurring most commonly after long bone fractures (usually tibia and fibula) in young adults and after hip fractures in elderly patients. Symptoms usually appear 1 to 2 days after an acute injury or after intramedullary nailing. Respiratory distress and hypoxemia are the earliest, most common manifestations. Acute respiratory distress syndrome (ARDS) may occur and is the usual cause of death. Neurologic involvement, manifesting as restlessness, confusion, or deteriorating mental status, also is an early sign, as are thrombocytopenia and a petechial rash. Fever, tachycardia, jaundice, retinal changes, and renal involvement may occur. Fat is seen in the urine in 50% of patients within 3 days of the injury. The incidence of full-blown fat embolism syndrome varies from 0.5 to 2% in patients with isolated long bone fractures to 5 to 10% in patients with multiple fractures. Management of fat embolism syndrome is primarily supportive, usually in an intensive care unit. The mortality rate is 20%, but most patients recover without severe sequelae.[63] No specific therapy has shown benefit.

Fracture Blisters

Fracture blisters are tense blisters or bullae that accompany high-energy injuries in areas of relatively little skin coverage over a fracture site. The ankle, elbow, foot, and knee (in that order) are the most common sites; all of these contain fewer hair follicles and sweat glands to anchor together the epidermal-dermal junction than do other limb locations.[64] Fracture blisters are believed, in many cases, to occur in the setting of increased underlying tissue pressure and may be a harbinger of compartment syndrome.

Early surgical intervention reduces the incidence of fracture blister formation.[64] In addition, the presence of a fracture blister requires an alteration of the surgical approach or a delay in surgery. Most experts discourage incisions through a fracture blister because such incisions seem to increase infection and skin breakdown. Measures to perform early surgery after high-energy

www.ketabpezeshki.com 66485457-66963820

injuries and to minimize increases in tissue pressures might reduce the incidence of this complication. Intact blisters should be covered with povidone-iodine solution and a sterile dressing. Unroofing the blister and applying coverage with silver sulfadiazine paste has been reported to decrease the incidence of complications.[64]

Complications of Immobilization

Fractures frequently result in long periods of immobilization. Immobility may lead to multiple medical problems, especially in elderly patients, including pneumonia, deep venous thrombophlebitis, pulmonary embolism, urinary tract infection, wound infection, decubitus ulcers, muscle atrophy, stress ulcers, gastrointestinal hemorrhage, and psychiatric disorders (Box 49-5). Early ambulation is a major goal of optimal orthopedic care.

Damage Control Orthopedic Surgery

Over the past few decades, the management of the multiply injured trauma patient has changed considerably. Historically, patients with multiple injuries were treated nonoperatively as it was believed they were too ill to tolerate surgery. In the 1970s, literature began to appear suggesting adverse outcomes as a result of prolonged recumbency. In addition, operative fracture fixation techniques were evolving, and this lead to the advent of early fracture stabilization and the notion of early total care of the polytrauma patient.[65] During the 1990s, the concept of damage control surgery came to the forefront of trauma surgical care. In a landmark paper, Rotondo and colleagues reported on the successful use of an abbreviated operation in patients with penetrating abdominal trauma to avoid the lethal triad of hypothermia, acidosis, and coagulopathy, and coined the phrase "damage control."[66] Similar principles were found to be applicable to the management of pelvic and long bone fractures in the polytrauma patient. Early total care with immediate definitive fixation of all major fractures saw a gradual move toward early temporary fracture stabilization, resuscitation of the patient to a stable physiologic state, then definitive fixation at a later time once the patient's physiology had been stabilized.[65] Temporary fracture stabilization is usually accomplished by application of external fixation devices to aid in hemorrhage control and tissue oxygenation, but the timing and optimal type of fracture surgery in the multiply injured trauma patient are still subjects of research.[67]

SUBLUXATION AND DISLOCATIONS

Nomenclature

Abnormal forces applied to joints may result in the loss of continuity between two articulating surfaces. Partial loss of continuity is termed *subluxation,* and complete loss is termed *dislocation*. In general, dislocations are named for the major joint involved, as in a dislocated shoulder or hip. In three-bone joints, the injury is named for the joint involved if the disturbance involves the two major bones, or, if the lesser bone is involved, the disturbance is named for that bone. Separation of the femur from the tibia is termed *dislocation of the knee,* whereas displacement of the patella from its normal articulation is termed *dislocation of the patella* (Fig. 49-10). At the elbow, separation of the olecranon from the humerus is a *dislocation of the elbow,* whereas separation of the radius from the humerus is termed *radial head dislocation.*

Dislocations and subluxations should be described according to the direction of the distal segment relative to the proximal segment or of the displaced bone relative to the normal structures. The injury shown in Figure 49-11 is termed *dorsal dislocation of the interphalangeal joint of the thumb.* Disruption of articulation also may occur in combination with a fracture. The term *fracture-dislocation* is used to describe this combination. If the overlying skin is broken in any way, dislocations, subluxations, or fracture-dislocations are described as *open* and constitute the same emergency as does an open fracture alone.

www.ketabpezeshki.com 66485457-66963820

Assessment

In most cases of dislocation, severe to excruciating pain is present because the joint capsule is stretched or torn. Movement of the joint exacerbates the pain. This useful sign is lost in an obtunded, intoxicated, or unconscious patient and may result in a missed diagnosis if a careful survey is not performed. Some dislocations, such as anterior shoulder dislocation, cause an obvious deformity, whereas others, such as posterior shoulder dislocation, may be subtle. Swelling of soft tissues also may obscure the diagnosis, such as in the tarsal-metatarsal region. Gentle passive testing of range of motion should be performed but never forced. Assessment for neurovascular function is similar to that for fracture. Certain dislocations (e.g., knee) are so commonly associated with vascular injuries that a careful assessment of blood flow is important in evaluating these injuries.

Plain radiographic studies detect most dislocations, provided that the correct views are ordered. Radiographs should be performed before and after attempts at reduction of first-time or complicated dislocations, unless there is neurovascular compromise. This confirms the diagnosis and ensures that associated fractures are documented before treatment is undertaken.

Treatment

Methods of relocating specific joints are reviewed in subsequent chapters, but a few principles apply. In general, the sooner a joint is relocated, the better. Later, swelling and muscle spasm make reduction more difficult. Also, pain is not adequately relieved until the dislocation is reduced. In the hip, early reduction is mandatory to restore vascular supply and to avert the complication of avascular necrosis. Before relocation is attempted, adequate analgesia or conscious sedation should be used. Nerve blocks are especially useful on the digits. The general principle of reducing a dislocation is to re-create and reverse the mechanism of injury, pulling the proximal end of the dislocated bone out and away from whatever is trapping it in its final resting place. This technique helps prevent interposition of soft tissues in the joint that can preclude reduction. As this maneuver is accomplished, the disarticulated surface is manipulated back or may snap back spontaneously toward its normal anatomic position. If the reduction is difficult, it should not be forced. A single good attempt is better than repeated attempts in an inadequately relaxed patient. Some joints cannot be reduced in the ED because (1) the opposing muscles are contracting too forcefully and general anesthesia is necessary to overcome these forces or (2) mechanical obstruction by a bony fragment or a torn piece of cartilage, tendon, joint capsule, or skin requires surgical removal for reduction to occur.[68]

SOFT TISSUE INJURIES

Sprains

Nomenclature

Ligamentous injuries resulting from an abnormal motion of a joint are termed *sprains.* A sprain is injury to the fibers of a supporting ligament of a joint. Sprains may be graded according to the severity of pathologic findings; clinically, however, the grades are often indistinct. *First-degree* sprains are characterized by minor tearing of ligamentous fibers with resultant mild hemorrhage and swelling. Minimal point tenderness can be elicited. Stressing the ligament produces some pain, but there is no opening or abnormal joint motion.

A *second-degree* sprain is a partial tear of a ligament, meaning more fibers are torn than in the first-degree injury. Clinical findings include moderate hemorrhage and swelling, tenderness, painful motion, abnormal motion, and loss of function. There may be a tendency toward persistent instability and recurrence, and prevention of these complications is a major goal of treatment.

A *third-degree* sprain describes the complete tearing of a ligament. Signs include a further exaggeration of the signs mentioned for second-degree sprain. In addition, stressing the joint reveals grossly abnormal joint motion, provided that this is not limited by pain or swelling. Analgesia and the evacuation of a hemarthrosis may be used to allow a more complete diagnosis of these injuries. Chronic joint instability is the rule if severe ligamentous injuries do not heal properly.

Assessment

The clinical presentation of a sprain of the extremity may be indistinguishable from that of a fracture. The injury frequently occurs during vigorous athletic activity when forces applied in opposite directions result in a joint being stressed in an abnormal or exaggerated direction. The patient may complain of hearing a "snap" or a "pop" at the moment of injury and conclude that a fracture is present. Other patients report "seeing stars" or "almost passing out" at the moment the injury occurred and may still be in extreme pain, appearing pale and diaphoretic if seen shortly after the injury. Analgesia should be provided to these patients. Evaluation should include a careful history of the exact sequence of events at the time of the injury and ascertaining the position of the extremity and the forces applied to it at that moment. A history of any sounds that accompanied the injury should be elicited. Examination of the joint should include stressing it to show abnormal motion. If radiographs are planned to rule out a fracture anyway or if exquisite pain is produced by mild attempts to apply stress, it is probably better to delay stressing until films have verified the absence of a significant fracture. Plain radiography is indicated in some, but not all, cases to rule out a fracture. It has been well demonstrated that clinical decision rules can reduce the number of radiographic studies without missing significant fractures.[69-72]

Avulsion fractures may occur concomitantly with sprains. In children, epiphyseal fractures occur more commonly than ligamentous disruption because of the relative ligamentous strength compared with the ease of disrupting the epiphyses. Arthroscopy or MRI is indicated in the follow-up evaluation of some of these injuries (e.g., for suspected cruciate ligament tears) when significant pain or disability is present.[73-75]

Treatment and Disposition

Specific management of sprains varis depending on the location and severity of the injury. In general, initial measures should include the traditional recommendations of ice, elevation, and analgesia. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective analgesics in many patients. Several studies have found a more rapid decrease in swelling, increased exercise endurance, and earlier return to work with use of NSAIDs.[76]

Immobilization through use of one of the following methods provides protection and comfort in the initial management of most injuries. Because the severity of injury is sometimes difficult to establish at the first visit, it is reasonable to immobilize the affected joint for the first 48 to 72 hours, after which the extent of injury can be better determined. At that time, early mobilization is often desirable, particularly in lateral ankle injuries because this leads to earlier return to work and athletic activities and better preservation of proprioceptive neuromuscular function.[77] Use of an inflatable "air cast" alone or in conjunction with an elastic ankle wrap has been shown to be effective in decreasing the symptomatic period.[78] For lower extremity injuries, protected weightbearing with crutches provides patients with comfort and avoids

www.ketabpezeshki.com 66485457-66963820

motion of the impaired part. In elderly patients, safe ambulation sometimes cannot be accomplished, and a short hospitalization or admission to a skilled nursing facility may be necessary.

For complete or nearly complete ligamentous disruption, urgent orthopedic consultation is usually mandatory. Less severe injuries can be followed up 3 to 7 days postinjury when acute swelling has subsided. Copies of plain films ordered in the ED should be sent with the patient if possible. Physical therapy and rehabilitative exercises sometimes are begun at these visits and carried on for several weeks. Because ligaments are relatively avascular, healing is slow, and patients with significant sprains should be informed of this. Sprains should be diagnosed as precisely as possible and should not be trivialized. Too often after radiographs have ruled out fracture of an affected extremity, the term *sprain* is applied indiscriminately or the patient is told that the injury is *only* a sprain, a misleading expression that should be avoided. Aside from creating false expectations regarding recovery, thoughtless mislabeling of injuries not in evidence may lead to missed occult fractures in adults or epiphyseal injuries in children.

Strains

Nomenclature

A *strain* is an injury to a musculotendinous unit resulting from violent contraction or excessive forcible stretch. The term *pulled muscle* sometimes is used interchangeably with muscle strain. These injuries are graded in a manner similar to sprains.

A *first-degree* (mild) strain is a minor tearing of the musculotendinous unit, characterized by minor swelling, local tenderness, and minimal restriction of movement. Findings increase along a continuum such that in a *second-degree* (moderate) strain, more fibers are torn, but without complete disruption; swelling, ecchymosis, and loss of strength are more marked. In a *third-degree* (severe) strain, the muscle or tendon is completely disrupted, with resultant separation of muscle from muscle, muscle from tendon, or tendon from bone.[79] An accompanying avulsion fracture may be present on radiographs in either second- or third-degree injuries.

Assessment

Signs and symptoms include pain, ecchymosis, swelling, and loss of function. A force applied to the muscle, either passive stress or active contraction, produces sharp pain at the site of injury even as the injured muscle may be relatively comfortable at rest. A palpable defect sometimes is present at the site of a complete rupture, which usually involves the region of the muscle-tendon junction, or a bunching up of the muscle may be appreciated. Ultrasound is increasingly being used to diagnose an assortment of soft tissue injuries, including rotator cuff tears, tendon ruptures, and muscle tears.[80,81] Among nonathletes, strains commonly are seen in patients who have either overstressed a muscle group or tried to generate excessive force in an unconditioned muscle. Examples are the weekend gardener or mover who experiences lower back strain on Monday morning, the aerobics student who strains the rectus muscles, and the weightlifter with chest wall pain resulting from pectoralis major strain. These are usually first-degree injuries, and the onset is slow. Rapid acceleration (e.g., in a tennis player) may result in a third-degree gastrocnemius or plantaris tear, whereas pushing off to jump is a common cause of ruptures of the Achilles tendon in a basketball player. A sudden violent attempt at lifting in an older individual can result in a complete biceps brachii disruption. Sudden generation of forces of which the thighs are capable results in second-degree strain of the hamstrings, quadriceps, or thigh abductor muscles.

In athletes, generation of tremendous contraction forces coupled with excessive forcible stretching (while the body may be either accelerating or "planting") results in severe strains. Involvement of almost any muscle group is possible, and the onset of such injuries is usually acute. Immediate removal from activity, application of ice, and rest of the affected limb for 48 to 72 hours usually are advised for prevention of further injury. A competitive athlete usually is unable to continue anyway because of the accompanying loss of function. After a brief rest period, however, early mobilization and rehabilitation should be encouraged.

Treatment and Disposition

Treatment depends on the degree of disruption, location, and functional loss. Most first-degree injuries respond in a few days to rest, application of ice, and, for some patients, analgesics. NSAIDs commonly are recommended and prescribed, although their efficacy for other than analgesic purposes is unproven. Second-degree strains are treated similarly, with protection against aggravating activity required for longer periods. Third-degree strains receive similar initial treatment in the ED plus early orthopedic consultation. Some of these injuries are amenable to surgical repair, whereas others may be treated with immobilization. The muscle affected and the age, occupation, and activity level of the patient all are factors in deciding whether surgical intervention is appropriate. Early mobilization is an important tenet in the treatment of muscle strains; its timing may be based on the ability to stretch the injured muscle as much as the uninjured contralateral muscle, and the use of the injured muscle without pain during basic movements.[79] Many athletes and their trainers believe, and it is universally espoused, that many strains can be prevented by proper preseason conditioning, warm-up, stretching exercises, and avoidance of overexertion, although limited scientific data exist to support these recommendations.[82]

Tendinitis and Tendinosis

Tendinitis is classically described as an inflammatory condition characterized by pain at tendinous insertions into bone, occurring in the setting of overuse.[83,84] It is now believed that the pathophysiology of this condition is more complex than mere overuse, with the roles of load and use affecting cell-matrix interaction.[85] Causative factors are believed to include aging, with decreased blood supply and decreased tensile strength; muscle weakness and imbalance; insufficient flexibility; male gender; obesity (in weight-bearing joints); smoking; malalignments; training errors; and improper equipment.[86,87] In addition, certain systemic diseases, including diabetes mellitus, chronic renal failure, rheumatoid arthritis, and systemic lupus erythematosus; steroid use; and occasionally fluoroquinolone use are associated with the development of tendinopathy.[88]

The histopathology of tendinitis is characterized by degeneration and disorganization of collagen fibers; infiltration by macrophages, plasma cells, and lymphocytes rather than leukocytes; and increased vascularity. Inflammatory changes are not a principal finding in tendinitis.[89] This evolving understanding of tendinitis in the future should allow for more logical treatment of these injuries aimed at the underlying pathophysiology. It also has led some authors to propose that chronic painful conditions of the tendon should be referred to as *tendinosis* rather than *tendinitis* or other terms previously used to describe this condition, including *tendonitis, degenerative changes, chronic tendinopathy,* or *partial rupture*.[86,90] In this chapter, *tendinitis* and *tendinosis* are used interchangeably.

Common sites for tendinitis are the rotator cuff of the shoulder, the Achilles tendon, the radial aspect of the wrist (de Quervain's tenosynovitis), and the insertion of the hand extensors on the

www.ketabpezeshki.com 66485457-66963820

lateral humeral epicondyle (tennis elbow). Also commonly involved in athletes are the patellar tendon, particularly in athletes engaged in jumping sports; the biceps femoris, semitendinosus, and semimembranosus (hamstring syndrome); the posterior tibial tendon (shin splint syndrome); the iliotibial band; and the common wrist flexors (medial epicondylitis) (involvement is seen in little league pitchers and golfers).[85] In some locations, most commonly the shoulder, calcium deposition occurs along the course of the tendon, resulting in a painful condition termed *calcific tendinitis*. This condition also may occur in the wrist, hand, neck, hip, knee, ankle, or foot.[91]

Physical examination reveals pain with motion and limitation of function and may include point tenderness and palpable crepitus over the involved tendon with motion. In general, a clinical test can be performed by forcible flexion of the involved muscle while keeping the point of insertion fixed or by operating the involved muscle against resistance. Either test should intensify the discomfort. Radiographs are usually negative. A small fleck of bone may suggest an avulsion, or the surface of the bone at the attachment may be roughened, indicating periostitis. As mentioned, there also may be calcium deposits along the course of the tendon, which should not be confused with an avulsion fracture. Ultrasound is sometimes useful in confirming the diagnosis of tendinitis. Although a normal tendon is characterized by a relatively homogeneous pattern, tendinitis is characterized by one or more of the following features: loss of the fibrillar echotexture, focal tendon thickening, diffuse thickening, focal hypoechoic area, irregular or ill-defined borders, or microruptures.[92]

There is little evidence to support any specific treatment for tendinosis. The classic approach consists of rest, ice, and NSAIDs initially, followed by rehabilitation and training and control of force loads to prevent recurrences. Although NSAIDs may be useful for a brief period at the onset of symptoms for their analgesic effects, no evidence exists that they significantly alter the pathophysiology of this condition, and no rationale exists for ordering them in patients at any risk for complications from this class of drugs.[93,94] Peritendinous local infiltrations of anesthetics and corticosteroids may be useful but should not be repeated too often because tendon rupture may occur. Injection therapy is especially useful in calcific tendinitis around the shoulder. Injection of steroids directly into the Achilles tendon should be avoided because of reports of partial or complete rupture after even a single injection. Some cases of calcific tendinitis that do not respond to conservative therapy may require either arthroscopic or open surgery.[95]

Bursitis

Bursitis is a painful inflammation of the bursa that may be traumatic, infectious, or related to systemic illness. Commonly involved sites include the olecranon, the greater trochanter of the femur, and the prepatellar and anserine bursae around the knee. Physical findings are tenderness and swelling over the involved bursa, whereas warmth and overlying erythema may signal infection. If infection is suggested, aspiration of the bursal fluid and Gram's staining and culture are recommended. Otherwise, treatment may be conservative and is similar to treatment for tendinitis, with ice, NSAIDs, or steroid injections. Most patients can be treated as outpatients.[96]

TREATMENT MODALITIES

Splinting and Bandaging

Suggested or confirmed fractures or dislocations should be splinted to avoid damage to muscles, nerves, vessels, and the skin. Splinting also may restore blood flow to ischemic tissue by removing pressure caused by a bone fragment resting against a blood vessel. In addition, splinting may relieve the pain associated with movement of fracture fragments.

Field Care

Splinting should begin in the field because it reduces the risk of further neurovascular compromise, prevents a closed injury from potentially being converted to an open one during transport, reduces the patient's pain, and facilitates subsequent ED assessment and imaging. Numerous commercial devices are available, and most ambulances carry an assortment of immobilization devices (Fig. 49-12). Minimal equipment includes long and short backboards, cervical collars, sandbags, and extremity splints. A half-ring traction splint also is essential. Inflatable air splints are favored by some authors because they are convenient, easy to apply, transparent, and radiolucent and because they tamponade low-pressure bleeding. Other authors prefer to avoid these devices because theoretically they could contribute to the development of a compartment syndrome. If used, inflatable splints should be inflated only by mouth and to the point that still permits indentation by gentle finger pressure.

Field personnel should splint possible fractures before the patient is moved. Severely angulated long bone fractures should be straightened in the field before they are splinted. Splints should

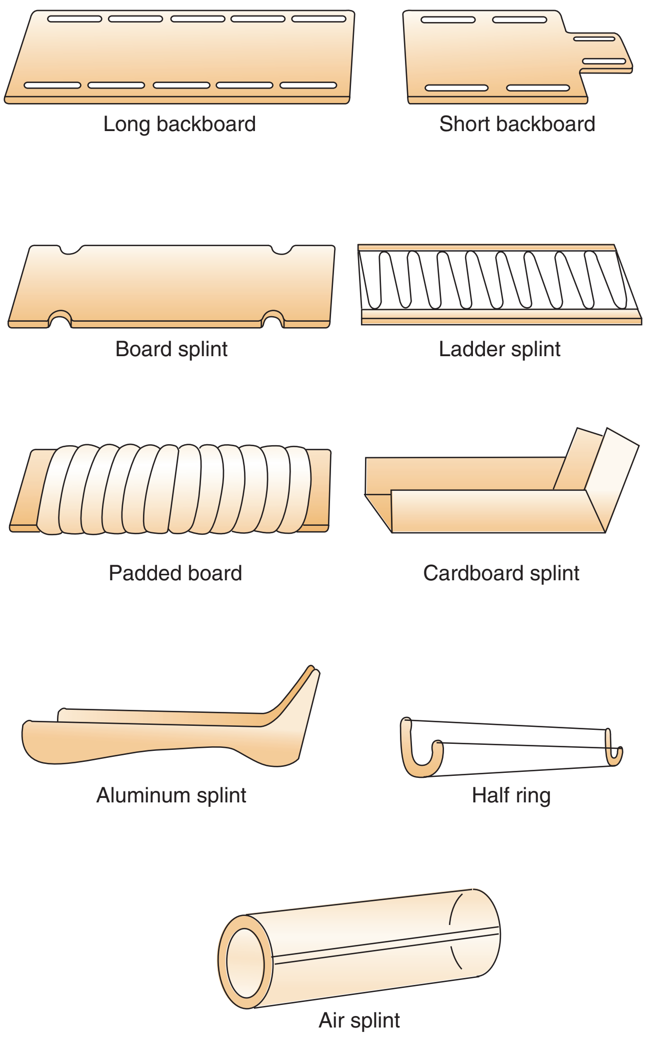

Figure 49-12. Commercial splints.

www.ketabpezeshki.com 66485457-66963820

be applied in such a way as to immobilize the joints above and below the fracture site to avoid motion of the involved bone. The skin should be padded to avoid local necrosis, and the splint should be secured by use of a circumferential wrapping material. This material should allow for some expansion and should not be applied in a constricting manner.

Emergency Department Care

In the ED, the indications for splinting are the same as in the field. All splints should be checked and if properly applied need not be changed. Hare traction should be removed in the ED because it may angulate femur fractures. Splinting or other immobilization is also used after diagnosis and treatment of injuries. In some cases a splint is all that is needed for definitive treatment. Injuries other than sprains and fractures (e.g., inflammatory and infectious processes, bites, burns, and repaired injuries of muscle bellies or tendons) also benefit from immobilization. Splints also can be used to improve function, such as with wristdrop that accompanies radial nerve palsy. When the injury is immobilized, it is important to stress elevation of the affected part to avoid edema formation. Many different devices and materials are available. Some devices that are commonly used are described next.

Upper Extremity

Sling-and-Swathe and Velpeau Bandages. Sling-and-swathe and Velpeau bandages are useful in immobilizing the shoulder, humerus, and elbow. They are commonly used after reduction of dislocated shoulders and to treat impacted fractures of the humeral neck. The axillae should be padded and powdered to avoid skin maceration. A commercial shoulder immobilizer also is available and is useful after reduction of a shoulder dislocation. Its advantages are ease of application and ease of removal and reapplication by the patient for bathing.

Clavicle Splint. Historically, middle third fractures of the clavicle routinely were initially treated with a figure-of-eight clavicle strap with or without the addition of a sling. This device is commercially available or can be fashioned from tubular stockinette. If used, a clavicle splint should be applied snugly enough to keep the shoulders back in the "at-attention" position, but not so tight as to compress the axillary artery or brachial plexus. Chafing of the skin can be avoided by padding and powdering the axillae. Superiority of the figure-of-eight clavicle strap over a simple sling has not been shown.

Plaster and Fiberglass Splints. Well-fitting, customized plaster splints can be fashioned easily to immobilize the elbow, forearm, wrist, and hand. The advantage of these splints is the ability to mold them to an exact size and shape (e.g., along the ulnar side of the forearm and hand to immobilize a midshaft fourth or fifth metacarpal fracture, the so-called "gutter splint"). Several commercially available products consist of multiple layers of plaster or fiberglass strips, inside a covering of foam and flannel, on a continuous roll that can be applied to any length. While the splint is still wet, a bandage is wrapped over it, and the splint is molded and held in the desired position as the plaster or fiberglass resin hardens.

Forearm and Wrist Splints. Numerous preformed splints are available for splinting fractures of the distal forearm and wrist. They are lightweight, neat, and easy to apply and are easily removed and replaced by the patient (Fig. 49-13).

Figure 49-13. Wrist splints.

Lower Extremity

Femur and Hip. Fractures of the femoral shaft can be immobilized with a traction device, such as the Hare traction splint or a similar appliance (Fig. 49-14). These devices should be applied in the field if possible; most ambulances carry them. The principle is that a proximal ring engages the ischial tuberosity for countertraction while the longitudinal traction is applied through the ankle by means of an ankle hitch. A commercial ankle hitch is recommended, but if one is not available, an improvised hitch can be fashioned with a triangular bandage or a wide piece of cloth tied in a Collins hitch. The patient's ankle bones, Achilles tendon, and arch of the foot should be padded, and the circulation should be checked to ensure it is intact. A properly applied splinting device relieves pain from a fracture rather than exacerbating it.

The Sager splint might offer advantages over other appliances in that it is applied to the medial and lateral aspect of the thigh rather than having a half-ring posteriorly (Fig. 49-15). The Sager splint is more acceptable for use in the presence of pelvic fractures and avoids compression of the sciatic nerve. Because the half-ring devices may produce angulation at the fracture site, the Sager device is purported to result in better alignment, although this has never been measured. The Sager splint is shorter and more compact than the Hare traction splint, rendering it more acceptable for certain transport helicopters and body scanners. Also, the amount of traction is metered at the ankle, and overtraction can be avoided.

Knee. Commercially available knee immobilizers can be used after acute injuries to provide firm but not rigid stabilization of the knee. The device is essentially a foam cylinder with medial and lateral aluminum stays, attached by Velcro straps, and spanning the upper thigh to upper ankle. This device is commonly used after trauma to let the knee "cool off" until a better physical examination or diagnostic study can be performed in a few days.

Another dressing that may be applied at the knee is the Jones "compression" dressing. Some authors believe the word *compression* should not be used here, to discourage application that is too tight. The Jones dressing is a bulky dressing that is used by some clinicians in situations when swelling is expected, including internal fixation procedures. The ability to flex and extend at the knee is maintained. The dressing consists of a thick layer of

www.ketabpezeshki.com 66485457-66963820

Figure 49-14. A, Hare traction splint. B, The commercial hitch is designed to protect the ankle and heel during traction.

Figure 49-15. A, Sager splint. B, Detail of distal Sager splint end with 10 pounds of traction applied.

absorbent cotton bandage (Webril) wrapped with an elastic bandage, followed by another layer of cotton bandage, followed by an additional elastic wrap. If more stability is required, slabs of plaster can be placed on the medial and lateral side of the limb, just under the last bandage. Caution is exercised because burns have been reported with this type of dressing when too many layers of plaster are used. A similar type of bulky dressing may be used for some injuries of the ankle and fractures of the calcaneus. In general, commercial knee immobilizers have replaced the Jones dressing in the treatment of acute knee injuries.

Ankle. Immobilization of the ankle can be accomplished by numerous means. Plaster splints can be used temporarily for the treatment of nondisplaced ankle fractures or for the treatment of severe sprains. These can be fashioned in the same manner as described for the upper extremity. An alternative method is to apply a full circular cast, bivalve it on either side, discard the anterior piece, and affix the posterior mold with an elastic bandage or bias-cut stockinette. Most ankle injuries should be splinted with the patient's ankle in neutral position. Injuries to the Achilles tendon, plantaris muscle, or gastrocnemius muscle initially should be treated with the foot held in slight equinus (plantar flexion) for comfort. The toes should be free to move distal to the metatarsophalangeal joints, and the proximal border should end below the tibial tubercle to avoid pressure on the peroneal nerve.

Adhesive strapping is an alternative method of ankle immobilization that provides good support and limitation of motion. Taping reportedly loses its "protective properties" with cyclic loading and sweating; although this is cited as a disadvantage, it may actually be helpful in encouraging and allowing early mobilization. This method is lightweight and not bulky, and a shoe can be worn over the material. Tape is applied in a noncontinuous manner, which allows for swelling and avoids constriction. First, the hair is shaved. Next, strips of tape are measured and torn off; 1½-inch or 2-inch cloth-backed adhesive tape or Elastoplast is used. Elastoplast is an elastic-backed tape, constructed to stretch only in the longitudinal direction; this serves to spring the foot back automatically to a neutral position if the foot is plantarflexed for any reason. The tape should be applied directly to the skin after a skin adherent, such as tincture of benzoin, is applied. The tape should lie flat because wrinkles may damage the skin (Fig. 49-16). The use of tape is associated with dermatologic complications, including itching or contact dermatitis, owing to adhesion of the tape to the skin.

For mild-to-moderate sprains, functional treatment options including elastic bandaging, soft cast, taping, or orthoses were found to be statistically better than immobilization for multiple outcome measures.[97] Lace-up supports may be more effective than elastic bandaging and result in less persistent swelling in the short

www.ketabpezeshki.com 66485457-66963820

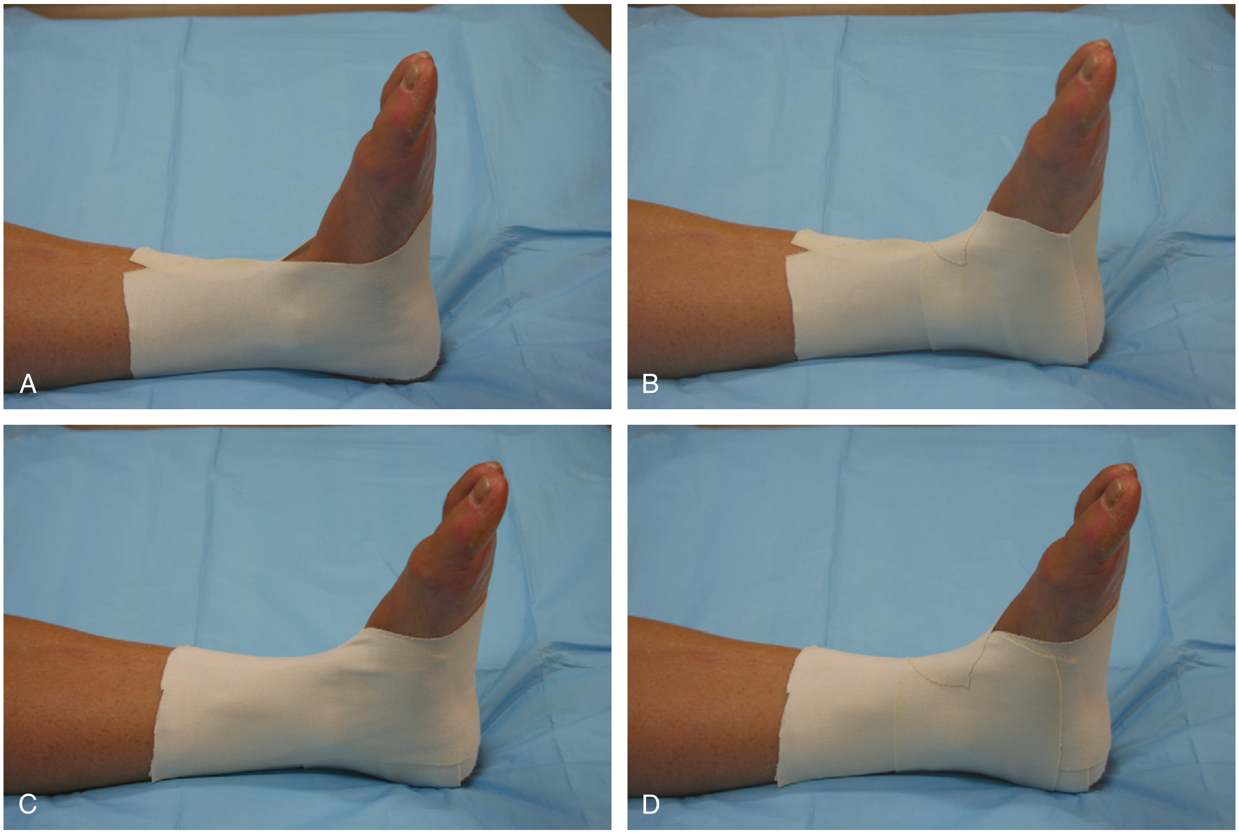

Figure 49-16. Application of adhesive strips to immobilize the ankle.

term as compared with semirigid ankle supports, elastic bandaging, and tape.[98]

For moderate-to-severe lateral ankle sprains, a commercial mechanical support composed of molded plastic with Velcro straps (e.g., AirCast Air-Stirrup) is more effective than elastic bandaging alone (Fig. 49-17).[77,99] This product may be worn in the patient's shoe and permits early weightbearing and return to activity. It is designed to permit dorsiflexion and plantar flexion but to limit inversion and eversion, a concept referred to as *functional bracing.* Some authors also find this device useful for athletic activities instead of adhesive taping to prevent recurrences.[78,100] Although these orthoses are relatively expensive, the cost might be more than offset by their ease of application, their reusability, and the benefit derived from earlier return to work.

Severe ankle sprains also may benefit from immobilization in a Cam Walker, which is a commercial appliance consisting of a layer of padding extending from the tibial tubercle to the metatarsal heads, supported by metal plates along the length of the lower leg. These plates articulate with a molded hard plastic boot at the ankle. The position of the foot can be adjusted as desired, and when set, the ankle is kept firmly immobile. The rounded undersurface of the boot allows for ambulation without movement of the ankle joint.

Casts

Plaster or synthetic (fiberglass) casts perform a function similar to splints in that they provide stability and pain relief. Casts are not mandatory for all fractures, and in situations in which they are, application is usually not an immediate necessity. Because they are circumferential, casts provide more effective immobilization of a fracture, but they require more skill and time to apply. Swelling and subsequent pressure under the cast are highest during the first 24 hours after injury. Complications of casting include compartment syndrome, thermal injury, pressure sores, bacterial and fungal infections (especially if a wound is present under the casted area), and pruritic dermatitis.[101] Plaster is applied as strips or rolls of cloth that are impregnated with a hemihydrate of calcium sulfate. When this cloth is dipped in lukewarm water, a creamy paste is formed that can be molded into a cast. An exothermic reaction takes place that causes the plaster to harden and can burn the skin.[102] Factors that have been shown experimentally to increase skin temperatures during plaster application are dip-water temperatures greater than 24° C, cast thickness greater than eight plies, and inadequate ventilation of the newly applied cast.[103] Immersing the plaster in water for too short a time or squeezing too much water out also may lead to generation of excess heat. To avoid pressure on the skin and over bony prominences, stockinette and layers of cotton sheet wadding (Webril) are snugly applied first. Padding that migrates under a formed cast can be uncomfortable and result in pressure sores. Padding alone does not prevent burns.

Variations of the basic cast exist. A window may be placed in the cast, and the cutout area may be used for access to skin wounds that require care during immobilization. Walking heels may be worked onto a lower extremity cast and should be placed in the center of the foot. Synthetic casts (fiberglass and other materials) are lightweight, durable, and water-resistant.[104] In addition, their setting temperatures are significantly lower, and they are less likely to produce burns. However, they are more expensive and more difficult to apply.

Patients with casts may visit the ED for complaints related to their casts; these usually are pain, local irritation, swelling, or numbness of the distal part. A cast that is too tight results in swelling, pain, coolness, and change in skin color of the distal parts. Pain also may be caused by the initial injury or by local pressure,

www.ketabpezeshki.com 66485457-66963820

Figure 49-17. Air cast ankle support. **A,** Lateral view. **B,** Anterior view.

or it may be a result of a developing compartment syndrome or wound infection. When a patient complains of pain, it is prudent to bivalve the cast and inspect the extremity. This is done by cutting the plaster and the padding on each side and removing half the cast at a time, with the other half used as a mold to keep the extremity immobile. Afterward, the bivalved cast can be held together with bias-cut stockinette or elastic wrap until a new cast is applied. If relieving external pressure does not alleviate symptoms, the diagnosis of compartment syndrome should be seriously considered. Casts may obscure wound infections, sources of sepsis, and even the source of tetanus. The clinician should not hesitate to bivalve the cast and inspect the extremity.

The need for mandatory routine cast checks 1 day after initial application has been questioned.[105] In a retrospective study of 250 patients, none experienced problems from neurovascular compression, although 24% required some alteration of the cast. In the study, it may be simply that the casts were applied incorrectly in the first place. It is probably advisable to continue routine cast checks if casts are applied in the ED.

Thermal Therapy

Some confusion exists as to the role of cryotherapy versus heat therapy in the treatment of acute orthopedic injuries. Part of this confusion arises because heat may be more soothing to the patient. Cold causes vasoconstriction, limiting blood flow and hemorrhage into the traumatized area. Metabolic requirements are reduced in cooled tissues, as is histamine, and less capillary breakdown occurs as a result. The sooner postinjury ice therapy is initiated, the more beneficial the reduction in metabolism will be.[106] Reduced blood flow also limits edema formation. Lower extravascular fluid pressure allows for better lymphatic drainage of injured areas. Cryotherapy produces three, and perhaps four, stages of sensation of which the physician and the patient should be aware. In the first stage, a cold sensation is noted for 1 to 3 minutes. The second stage consists of a burning or aching sensation for 2 to 7 minutes after the application of cold. This stage is uncomfortable but needs to be endured if the benefits of the next two stages are to be received. Heat therapy, by contrast, is soothing, and patients are likely to prefer this to the second stage of cryotherapy. The third stage begins 5 to 12 minutes after the application of ice and produces local numbness or anesthesia. The pain-spasm cycle is interrupted. While the patient is under this anesthetic effect, passive exercise may be desirable. This exercise helps to prevent atrophy, mobilize edema, clear injury debris, and reduce adhesions. However, several reviews of cryotherapy for soft tissue injury all reflect the lack of adequate science in establishing recommendations for cryotherapy. Application of ice appears to be effective in reducing pain, but there is no credible evidence that it accelerates healing.[107-109]

A fourth stage sometimes occurs 12 to 15 minutes after intense cryotherapy is begun, consisting of reflex deep tissue vasodilation without a corresponding increase in metabolism (reminiscent of the situation in rewarming shock). Because of this, a maximum of 10 to 15 minutes of cold application per treatment usually is advised. A systematic review of small, limited-quality studies assessed cryotherapy in the management of soft tissue injuries noted wide variation on the optimal mode, duration, and frequency of ice application.[109] Therefore recommendations for an optimal cryotherapy protocol cannot be made.

Absolute contraindications to cryotherapy include severe cold allergy (with hives and joint pain) and Raynaud's phenomenon and disease. Relative contraindications include some rheumatoid conditions and paroxysmal cold hemoglobinuria with renal dysfunction and secondary hypertension. Anesthetic skin in a paralyzed or comatose patient is at risk with ice therapy. Complications

www.ketabpezeshki.com 66485457-66963820

of cryotherapy can include skin burns and nerve damage but are rare, especially in the athletic population most at risk for serious injuries. Heat increases blood flow and the inflammatory response and edema. Warm tissues and cells have a higher metabolic rate and increased requirements of nutrients and oxygen. Ice, rather than heat, is the method of choice of most authorities in the acute treatment and rehabilitation of acute orthopedic injuries and should be initiated as soon as possible for maximum benefit.

Autologous Blood Product and Growth Factors

In recent years, growth factors have been used for the management of soft tissue injury related to acute trauma and overuse injury. Platelets contain growth factors in their alpha-granules, including insulinlike growth factor-1, basic fibroblast growth factor, platelet-derived growth factor, epidermal growth factor, vascular endothelial growth factor, and transforming growth factor-β_1, and these are thought to help the regeneration of tissues that otherwise have low healing potential.[110,111] Growth factors can be delivered as a preparation of platelet rich plasma (PRP), autologous blood injection, and autologous conditioned serum. PRP injections have been described in patients with patellar and elbow tendinosis, Achilles tendon injury, and acute ligamentous and muscle injuries, and they have also been administered intraoperatively during anterior cruciate ligament reconstruction and rotator cuff repair.[112-114] Theoretic advantages to the use of PRP include faster recovery and improved functional outcome, but evidence supporting the use of PRP in different tissues is limited and further studies are required before conclusions are drawn.

KEY CONCEPTS

- Consultation with an orthopedist should be sought for the treatment of most long bone fractures, open fractures, injuries with joint violation, and injuries with neurovascular compromise.
- Compartment syndrome is associated most commonly with a closed long bone fracture of the tibia but also is well described in the thigh, forearm, arm, hand, and foot and can occur with soft tissue trauma alone. Elevation of a limb with resultant reduction in the local arteriovenous gradient may be counterproductive and may exacerbate compartment syndrome.
- Because of their blood supply, certain bones may undergo avascular necrosis after fracture, especially if fractures are comminuted and go untreated for any length of time. The femoral head, talus, scaphoid, and capitate are particularly prone to this complication.
- Fat embolism syndrome is a serious manifestation of fat embolism, occurring most commonly after long bone fractures in young adults (usually tibia and fibula) and after hip fractures in elderly patients. ARDS is the earliest, most common, and serious manifestation. Neurologic involvement, manifesting as restlessness, confusion, or deteriorating mental status, is also an early sign, as are thrombocytopenia and a petechial rash.
- In children, epiphyseal fractures occur more commonly than ligamentous disruption because of the relative ligamentous strength compared with the ease of disrupting the epiphyses.

Chapter 50

Hand

Thomas Mailhot and Everett T. Lyn

PERSPECTIVE

The hand is intricate, dynamic, and unique in function. It combines extreme mobility, precision, power, and sensation and is used to express and execute. Because the hands are used more to manipulate the environment than the rest of the body, they are commonly injured. Function depends on intact relationships among intrinsic structural components, musculotendinous units originating from more proximal areas, and motor and sensory connections with the central nervous system. Restoration of function rather than appearance is the primary goal in management of hand injuries and infections. Early recognition and timely initiation of therapy for limb-threatening conditions are essential to an optimal outcome. The fate of the injured hand depends largely on the physician who provides initial care. Mismanagement may result in unnecessary functional loss that may not be recoverable, even with the best convalescent care. An understanding of the functional anatomy of the hand is necessary for the appropriate evaluation and management of these disorders.

Epidemiology

Overall, hand injuries are reported to represent 5 to 10% of visits to an emergency department (ED), and approximately 6% of the patients have deep, significant injuries.[1] Injuries have environmental, occupational, and recreational causes and are seen in all age groups. The spectrum of injury includes infections, lacerations, fractures, crush wounds, amputations, and burns. It is estimated that 10% of all patients with hand injuries require referral to a hand specialist, and most patients referred from EDs have fractures.[2] The disability potential of hand injuries generally is high; such disability may involve loss of strength, flexibility, or sensation. According to available data, hand injuries account for 19% of lost-time injuries and for 9% of worker compensation cases.[3] Approximately 3 to 4 million working days are lost each year as a result of hand injuries.[4] Overall, hand and fingers are the most frequent body parts injured in the workplace and cared for in EDs.[5]

PRINCIPLES OF DISEASE, FUNCTIONAL ANATOMY, PHYSIOLOGY, AND EXAMINATION OF THE HAND

Terminology

To avoid confusion, it is important that standard terminology for the surface anatomy of the hand be used (Fig. 50-1). The back of the hand and fingers is called the *dorsal surface,* and the palm side is called either the *palmar* or the *volar surface*. The borders of the hand are *radial* and *ulnar.* The five digits often are designated by numerals, but common names are preferable: I (thumb), II (index finger), III (long or middle finger), IV (ring finger), and V (little finger). Each finger has three joints: the metacarpophalangeal (MCP), the proximal interphalangeal (PIP), and the distal interphalangeal (DIP) joints. The thumb has an MCP joint and only one interphalangeal (IP) joint. There are proximal, middle, and distal phalanges in the fingers and only a proximal and a distal phalanx in the thumb. The *thenar mass* or *eminence* refers to the muscular area on the palmar surface overlying the thumb metacarpal. The *hypothenar eminence* is the muscle mass on the palmar surface overlying the little finger metacarpal.

Hand and digit motion has been standardized and is illustrated in Figures 50-2 through 50-6. The carpometacarpal (CMC) joint is more mobile in the thumb than in the other fingers and is the key to the grasp and dexterity that characterize the human hand. Motions of this joint include *palmar abduction* (also called *flexion*), *radial abduction, retroposition (extension), adduction,* and *opposition* (see Fig. 50-6). The IP joints are essentially hinge joints and are capable of only two motions: flexion and extension.

Structural Framework

Skin Cover

The hand has two skin surfaces, each with different functions. The skin of the palm is thick compared with the dorsal skin and is stabilized by fibrous connections on its deep surface. The skin creases in the palmar aspect of the hand are largely transverse and represent adherence between skin and underlying fascia, without intervening adipose tissue. These features facilitate flexion and limit the development of inflammatory edema in the palm.[6] The other noteworthy characteristic of the palmar skin is the unique arrangement of epithelial ridges of the dermis that form cutaneous striations. These ridges have forensic importance in the pulp as "fingerprints" and play an important role in increasing friction for grasping objects.[7]

The dorsal skin is relatively thin and mobile, permitting motion of the various joints. As a path of least resistance, the dorsum of the hand also swells easily after inflammation or trauma, which may limit flexion of the MCP joints.[7] In addition, infection in the palmar aspect of the hand may cause dorsal swelling; this finding can be misleading without a careful physical examination.

Skeleton

The hand and wrist contain 27 bones: 14 phalangeal bones, 5 metacarpal bones, and 8 carpal bones (Fig. 50-7). The eight small

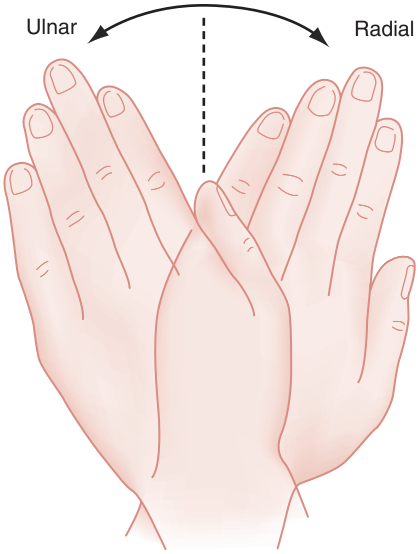

Figure 50-3. Ulnar and radial deviation of the hand.

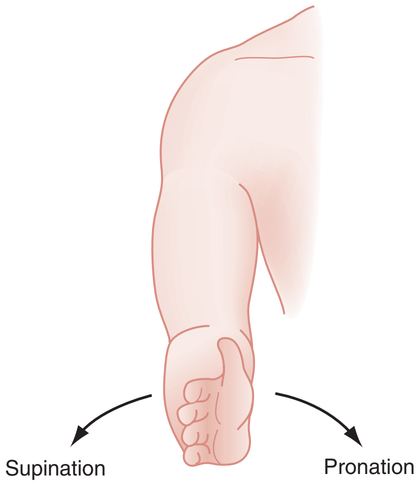

Figure 50-2. Supination and pronation of the hand.

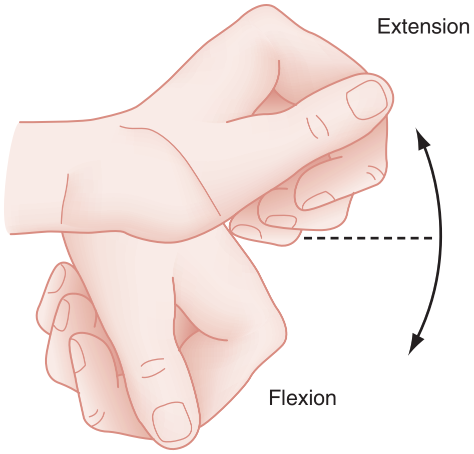

Figure 50-4. Wrist extension and flexion.

carpal bones in the region of the wrist are strongly united to one another by ligaments. These bones form synovial joints and are arranged in two rows, proximal and distal, with four bones in each row. Together the bones of the carpus present a concavity on their volar surface, which is bridged by a strong membranous band, the flexor retinaculum. In this way, the bridge and the bones form a tunnel, known as the *carpal tunnel,* through which pass the median nerve and the long flexor tendons of the fingers. The IP joints are inherently more stable than the MCP joint by virtue of their bicondylar configuration, which gives a modified tongue-in-groove appearance (Fig. 50-8).

The soft tissue supporting these joints includes the capsular ligamentous structures, which afford stability, and the tendinous structures, which generate mobility. The metacarpal and IP joints are stabilized on both sides by collateral ligaments and anteriorly by a palmar fibrocartilaginous "volar plate." Because of anatomic

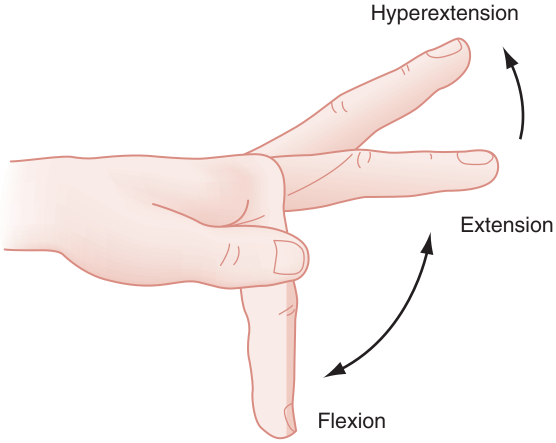

Figure 50-5. Finger flexion is volar and occurs at the metacarpophalangeal joint; extension and hyperextension are as shown.

www.ketabpezeshki.com 66485457-66963820

differences between the metacarpals and phalanges, the IP collaterals are tight throughout the entire range of motion, whereas the collaterals of the MCP joint are tightest in flexion (Fig. 50-9). The IP joints are hinges, but the MCP joint has additional side-to-side mobility and rotational movement to facilitate efficient grasp.[7] The clinical importance of these differences is that for minimization of the development of contractures after joint injuries, the preferred position of immobilization of the PIP joints is extension, whereas the MCP joints are more properly placed in flexion.

The structure and arrangement of the metacarpals are noteworthy. The metacarpals participate in three arches: the proximal (carpal) and distal (metacarpal) transverse arches and the longitudinal arch[6] (Fig. 50-10). The index and long finger metacarpals form a fairly immobile segment because of their ridged articulation with the carpals. The adjacent metacarpals are more mobile. This unique anatomy gives the human palm a longitudinal and transverse concavity when the thumb is alongside the index finger; however, this changes to an oblique gutter when the thumb is extended.

The small bones of the child's hand differ significantly from the bones of the adult and from other long bones because of the presence of an epiphysis or growth plate at one end of the bone. The phalangeal epiphyses and the thumb metacarpal epiphysis are located at the proximal end, and the finger metacarpal epiphyses are located at the distal end of the bone (Fig. 50-11). In boys the proximal phalangeal epiphysis appears at 15 to 24 months and fuses at 16 years. In girls it appears at 10 to 15 months and fuses at 14 years.[8] The time of appearance and fusion is related to skeletal maturity and can be judged accurately until puberty from hand and wrist radiographs, because the sequence of development is age-specific.[9]

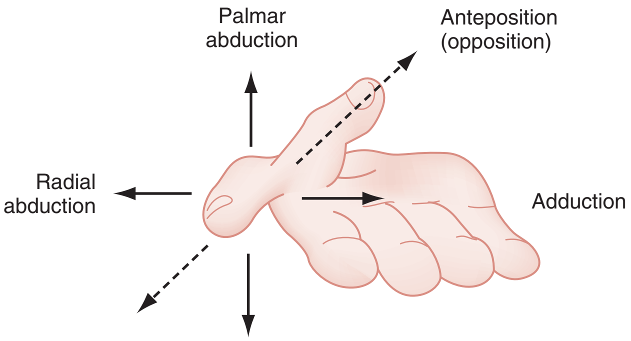

Figure 50-6. Perpendicular view of thumb mobility.

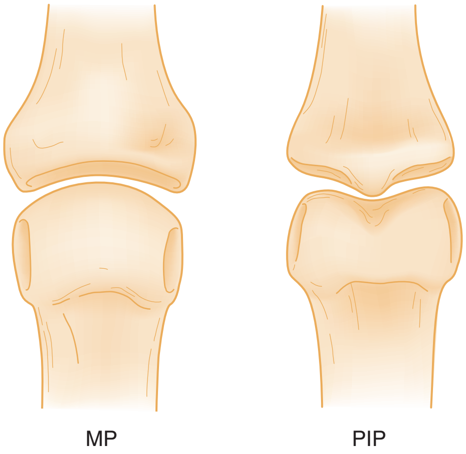

Figure 50-8. The metacarpophalangeal *(MP)* and proximal interphalangeal *(PIP)* joints are quite different structurally. The PIP joint has a bicondylar configuration, making it inherently more stable than the globular MP joint. (From DeLee JC, Drez D Jr: Orthopedic Sports Medicine: Principles and Practice, 2nd ed. Philadelphia, Saunders, 2003.)

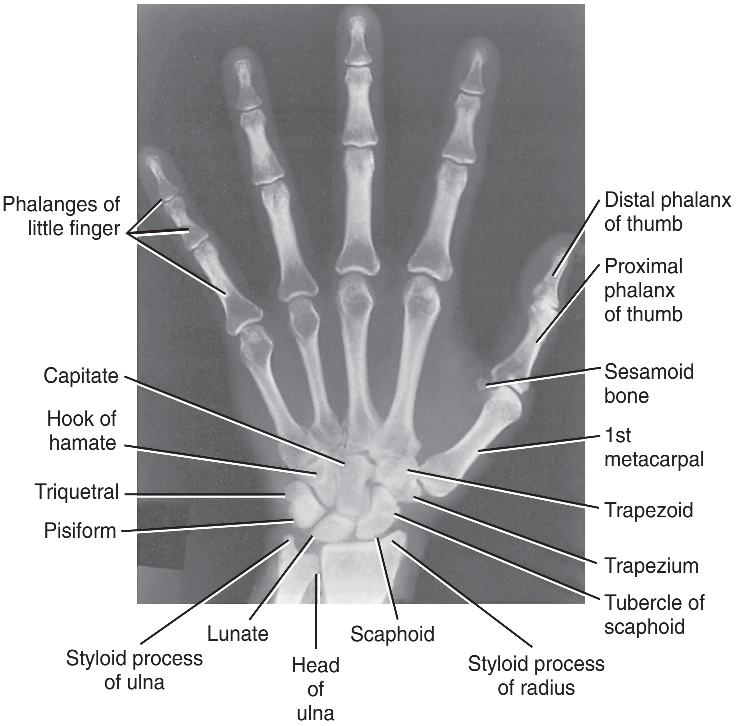

Figure 50-7. Posteroanterior radiograph of the wrist and hand with the forearm pronated. (From Snell RS, Smith MS: Clinical Anatomy for Emergency Medicine. St. Louis, Mosby, 1993, p 650.)

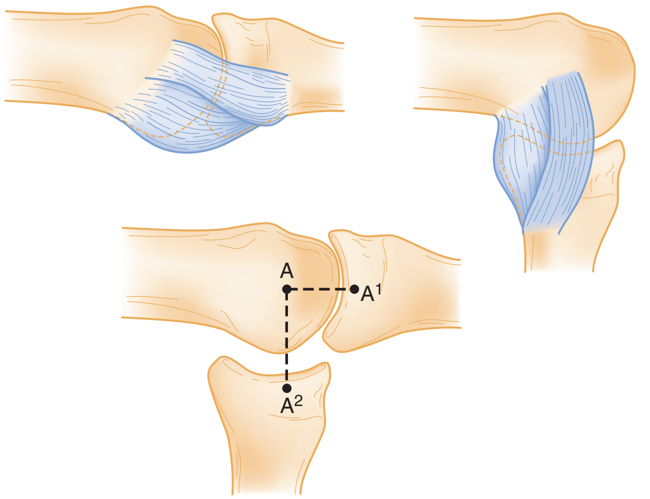

Figure 50-9. The shape of the metacarpal head is eccentric, resulting in a cam effect that makes the collateral ligaments more taut in flexion than in extension. Distance A-A^1 is less than A-A^2. The cam effect is not present in the proximal interphalangeal joint. (From DeLee JC, Drez D Jr: Orthopedic Sports Medicine: Principles and Practice, 2nd ed. Philadelphia, Saunders, 2003.)

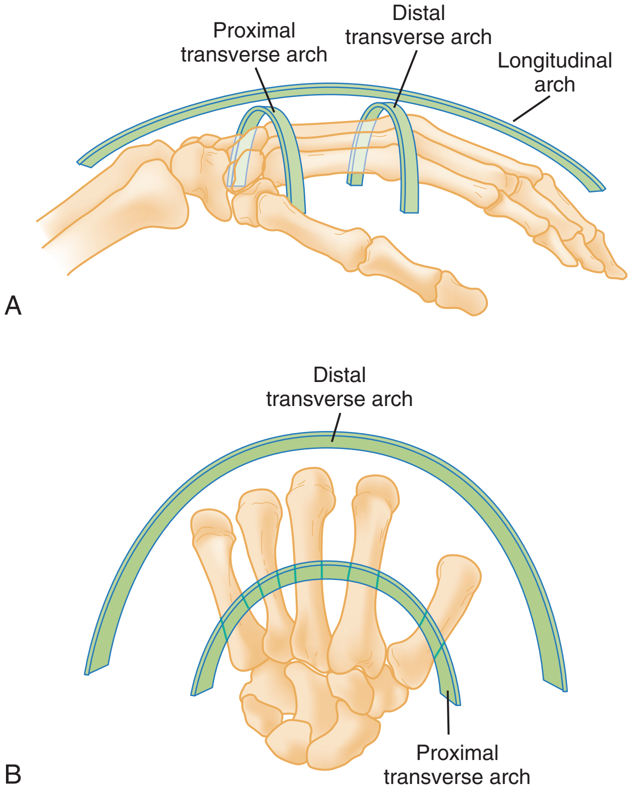

Figure 50-10. The three arches of the metacarpals. **A,** Sagittal view. **B,** Transverse view. (From American Society for Surgery of the Hand: Regional Review Course in Hand Surgery Syllabus, 10th ed. Aurora, Colo, ASSH, 1990.)

Figure 50-11. Normal location of the epiphysis of the hand. All of the phalangeal epiphyses are located at the proximal end. The metacarpophalangeal epiphyses all are distally situated, however, except for that of the thumb, which is proximal. (From Harris WH, Harris CC: The Radiology of Emergency Medicine. Baltimore, Williams & Wilkins, 1993, p 440.)

Muscle and Tendon Function

The muscles that power the hand may be divided into extrinsic and intrinsic muscles. The intrinsic muscles have their origins and insertions within the hand. The extrinsic muscles have origins in muscle bellies in the forearm and tendinous insertions on bones in the hand. They are divided further into extrinsic flexor and extensor muscles. The flexors of the digits in the hand lie on the volar surface of the forearm; the extensors are on the dorsal surface.

Intrinsic Musculature. The intrinsic muscles of the hand include the muscles of the thenar and hypothenar eminences, the adductor pollicis, the interossei, and the lumbricals (Fig. 50-12). The thenar muscles cover the thumb metacarpal. This group includes the abductor pollicis brevis, opponens pollicis, and flexor pollicis brevis. These muscles originate in the flexor retinaculum and on the carpal bones and insert at the base of the first metacarpal and first proximal phalanx. They act in concert with the long flexors and extensors to carry the thumb through its intricate range of motion. The muscles are evaluated by palpation of the thenar eminence for contraction as the patient brings together the tips of the thumb and little finger. They also can be tested by asking the patient to place the dorsum of the hand on a flat surface and to raise the thumb up straight to form a 90-degree angle with the palm. The thenar muscles usually are innervated by the motor branch of the median nerve. In some cases they may be partially innervated by the ulnar nerve.

The adductor pollicis arises from the index and middle finger metacarpals and inserts on the first proximal phalanx. This muscle is innervated by the ulnar nerve. Thumb adduction is tested separately by having the patient forcibly hold a piece of paper between the thumb and radial side of the index proximal phalanx. If the adductor pollicis is weak or nonfunctioning, the thumb IP joint flexes with this maneuver (Froment's paper sign).[10] In this evaluation, the two hands should be compared.

The lumbrical muscles arise from the sides of the flexor digitorum profundus (FDP) tendons; the interossei muscles lie between the metacarpal bones and originate from them. Both of these muscle groups insert in the extensor expansions of the index, middle, ring and little fingers and act on the fingers to flex the

www.ketabpezeshki.com 66485457-66963820

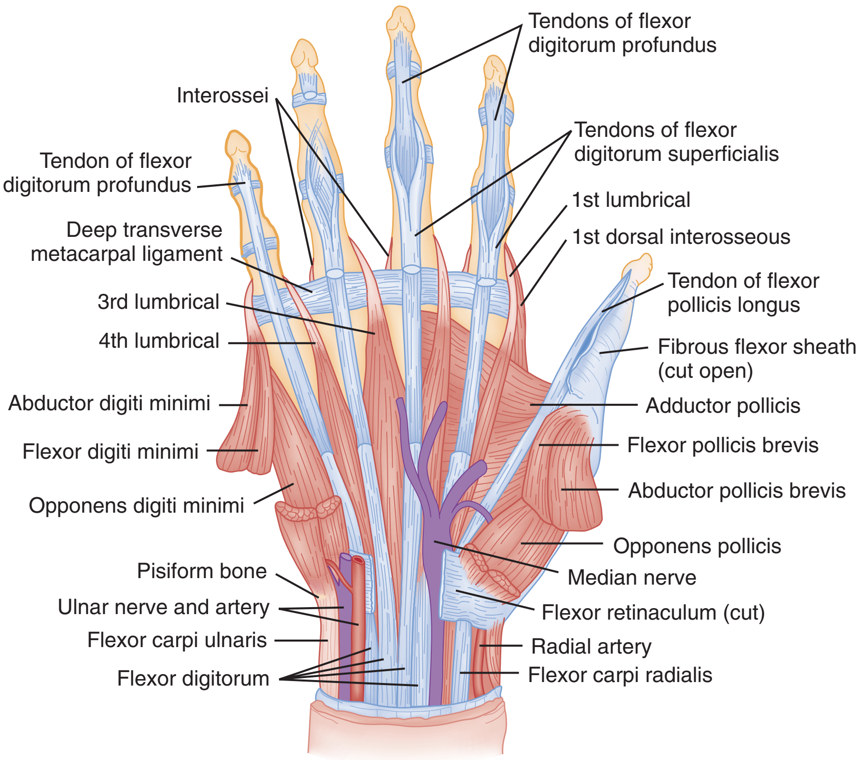

Figure 50-12. Anterior view of the palm of the hand. The palmar aponeurosis and the greater part of the flexor retinaculum have been removed to display the median nerve, the long flexor tendons, and the lumbrical muscles. Segments of the tendons of the flexor digitorum superficialis muscle have been removed to show underlying tendons of the flexor digitorum profundus muscles. (From Snell RS, Smith MS: Clinical Anatomy for Emergency Medicine. St. Louis, Mosby, 1993, p 641.)

MCP joints and extend the IP joints. The radial two lumbricals are innervated by the median nerve, and the ulnar two are innervated by the ulnar nerve. The seven interossei (three palmar and four dorsal) can be considered together. They lie on either side of the finger metacarpals and are innervated by the ulnar nerve. The dorsal interossei abduct the fingers away from the midline; the volar muscles adduct the fingers. For an accurate test that isolates their function from the extrinsic muscles, the patient should place the palm flat on a table, extend the digit, and move it from side to side.

The hypothenar group of intrinsic muscles includes the opponens digiti minimi, the flexor digiti minimi, and the abductor digiti minimi. These muscles arise from the carpal bones and in the flexor retinaculum and insert on the proximal phalanx and metacarpal of the little finger. The flexor digiti minimi and abductor digiti minimi flex the proximal phalanx and abduct the little finger respectively. The three muscles are evaluated as a group by having the patient place the wrist in a neutral position and abduct the little finger (move it away from the other fingers) against resistance. This muscle mass is palpated at that time, and a dimpling of the hypothenar skin is noted. All of the intrinsic muscles of the little finger are innervated by the ulnar nerve.

Extensor Tendons. The extensor tendons are on the dorsal side of the forearm, wrist, and hand. The nine extensor tendons cross the wrist joint dorsal to its axis of rotation, pass under the extensor retinaculum, and are separated on the dorsum of the hand by a series of six fibro-osseous canals or compartments. Figure 50-13 outlines the compartments and their contents. The fibrous roof of these compartments prevents the tendons from bowstringing dorsally during active finger extension, particularly when the wrist also is extended.

The first dorsal wrist compartment contains the tendons of the abductor pollicis longus, which inserts at the dorsal base of the thumb metacarpal, and the extensor pollicis brevis, which inserts on the proximal phalanx of the thumb. The abductor pollicis longus serves to abduct the thumb ray, or thumb digit and metacarpal bone, radially, and the extensor pollicis brevis acts primarily to extend the thumb ray at the MCP joint. These tendons are evaluated by having the patient abduct and extend the thumb with resistance applied to the thumb; they can be palpated on the radial side of the wrist during this maneuver.

Two tendons lie in the second compartment: the extensor carpi radialis longus and brevis. These tendons insert at the dorsal base of the index and middle metacarpals. They act primarily to extend and deviate the wrist radially. These tendons can be palpated by having the patient extend the wrist against resistance while making a fist.

In the third compartment, a single tendon, the extensor pollicis longus, arises from the deep muscles of the midforearm, passes around a bony prominence on the dorsum of the wrist termed *Lister's tubercle,* and inserts on the base of the distal phalanx of the thumb. This tubercle can be palpated just proximal to the wrist joint. The extensor pollicis longus forms the dorsal border of the anatomic snuffbox, and the abductor pollicis longus forms the volar border (Fig. 50-14). The floor of this area contains the radial artery and two carpal bones, the scaphoid and trapezium. The extensor pollicis longus functions to extend and adduct the entire first ray and extend and hyperextend the IP joint of the thumb. This muscle is evaluated by placing the hand flat on a table and having the patient lift only the thumb off the surface. Because the abductor pollicis brevis and the adductor pollicis add terminal extension, complete laceration of the extensor pollicis longus tendon may not eliminate the patient's ability to extend the thumb.[11]

The tendons that extend the fingers—the extensor indicis proprius and the extensor digitorum communis—are in the fourth compartment. The extensor digitorum muscle divides into four tendons proximal to the wrist. In the dorsum of the hand, these tendons are joined distally by fibrous interconnections called *juncturae tendinum* which help stabilize them to their insertions in the extensor expansions of the index, middle, ring, and little fingers. The extensor digiti minimi is contained in the fifth dorsal compartment. Both the extensor indicis proprius and the extensor digiti minimi typically lie ulnar to their respective common

www.ketabpezeshki.com 66485457-66963820

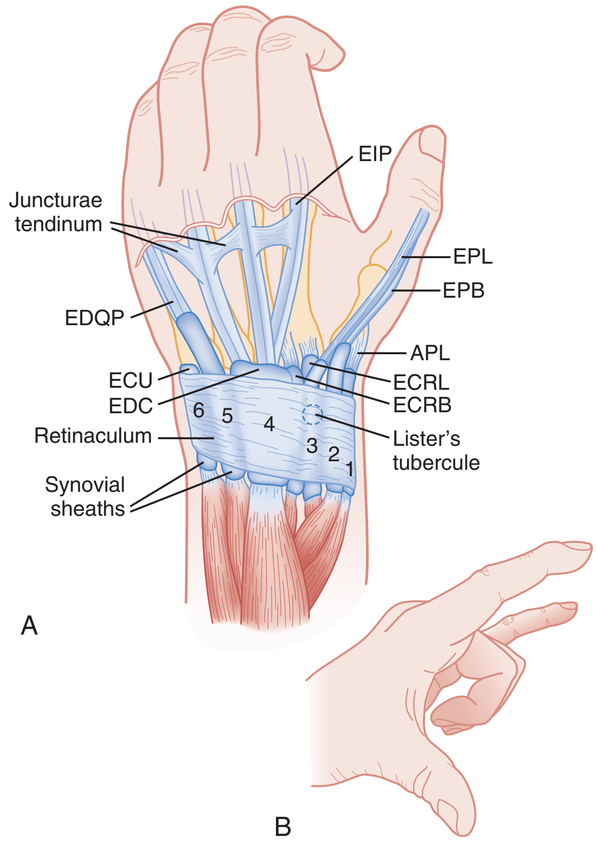

Figure 50-13. A, The extensor tendons gain entrance to the hand from the forearm through a series of six canals, five fibro-osseous and one fibrous (the sixth dorsal compartment, which contains the extensor digiti quinti proprius *[EDQP]*). The first compartment contains the abductor pollicis longus *(APL)* and extensor pollicis brevis *(EPB);* the second, the radial wrist extensors; the third, the extensor pollicis longus *(EPL),* which angles around Lister's tubercle; the fourth, the extensor digitorum communis *(EDC)* to the fingers and the extensor indicis proprius *(EIP);* the fifth, the EDQP; and the sixth, the extensor carpi ulnaris *(ECU).* The communis tendons are joined distally near the metacarpophalangeal joints by fibrous connections called *juncturae tendinum.* Beneath the retinaculum, the extensor tendons are covered with a synovial sheath. **B,** The proprius tendons to the index and little fingers are capable of independent extension, and their function may be evaluated as depicted. With the middle and ring fingers flexed into the palm, the proprius tendons can extend the ring and little fingers. *ECRB,* extensor carpi radialis brevis; *ECRL,* extensor carpi radialis longus; *EDQP,* extensor digiti quintus proprius. (From Doyle JR: Extensor tendons-acute injuries. In Green DP [ed]: Operative Hand Surgery. New York, Churchill Livingstone, 1993, p 1927.)

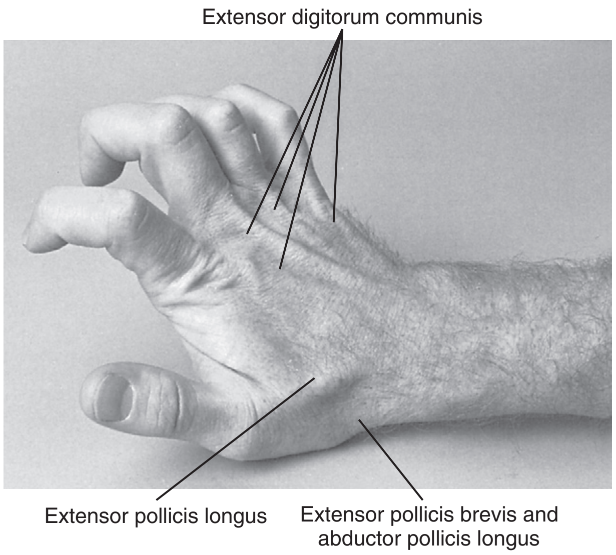

Figure 50-14. Surface anatomy of the wrist and hand. The tendons that are palpated with the thumb abducted and extended form an anatomic snuffbox.

extensor tendons. The dual extensor system for the index and small fingers gives these two digits extension independent of the other digits. The middle finger and especially the ring finger have considerably limited independent extension. The motion restriction is because of the juncturae, which also prevents retraction of the proximal tendon end after distal transection of an extensor. Complete severance of an extensor proximal to the juncturae can be associated with normal MCP joint extension.[7] This extension occurs through the juncturae connections. The extensor digitorum communis tendons can be evaluated by asking the patient to straighten out all of the fingers. The function of the extensor indicis proprius can be isolated from the common extensors by asking the patient to make a fist and then to point the index finger. The extensor digiti minimi is examined by having the patient straighten the little finger while the hand is closed into a fist.

The extensor mechanism of each digit is a complex interrelationship of muscle-tendon units of the long extrinsic extensor tendons and the intrinsic system (Fig. 50-15). The extensor expansion divides into a central slip that attaches to the middle phalanx and two lateral bands that join with the tendons of the lumbrical and interosseous muscles and attach to the base of each distal phalanx. The interossei and lumbrical muscles insert in the lateral aspects of the dorsal hood. Most of the power of the common extensors serves to extend the MCP joint. Distal digit extension is provided by continuation of the lateral band mechanism and the oblique retinacular ligament. Because of this complex anatomy, injuries involving the extensor mechanism require meticulous repair.

The sixth compartment contains the extensor carpi ulnaris. This tendon passes distal to the head of the ulna on the ulnar aspect of the wrist and inserts on the base of the little finger metacarpal. The extensor carpi ulnaris functions to extend and deviate the wrist ulnarly. This tendon is evaluated by having the patient extend and push the hand to the ulnar side against resistance; the tendon can be palpated distal to the ulnar styloid process.

Flexor Tendons. The flexor tendons reside on the volar side of the forearm and cross the wrist joint volar to its axis. In general, 12 tendons function to flex the wrist and digits; three of them—the flexor carpi radialis, flexor carpi ulnaris, and palmaris longus—primarily flex the wrist and deviate the wrist radially or ulnarly (Fig. 50-16). The remaining tendons pass into the digits through the carpal tunnel. A single tendon, the flexor pollicis longus, inserts on the distal phalanx of the thumb, and two flexor tendons go to each remaining finger. The flexor digitorum superficialis (FDS) tendons bifurcate near the base of the proximal phalanges and surround the tendons of the FDP before inserting on the middle phalanges of the index, middle, ring, and little fingers (Fig. 50-17). The FDS flexes all the joints it crosses, including the wrist, PIP joints, and MCP joints. The profundus tendons lie deep to the superficialis tendons over most of their course in the forearm. At the level of the MCP joint, they perforate the superficialis tendon to emerge to a superficial position. They insert at the base of the distal phalanx and act primarily to flex the DIP joint and all joints flexed by the FDS. From the level of the MCP joint distally, the two flexor tendons become enclosed in a fibrous flexor sheath lined by synovium. Regions of thickening in this sheath form pulleys that help prevent bowstringing of the flexor tendons across the joint and assist smooth, effective flexion (Fig. 50-18).

www.ketabpezeshki.com 66485457-66963820

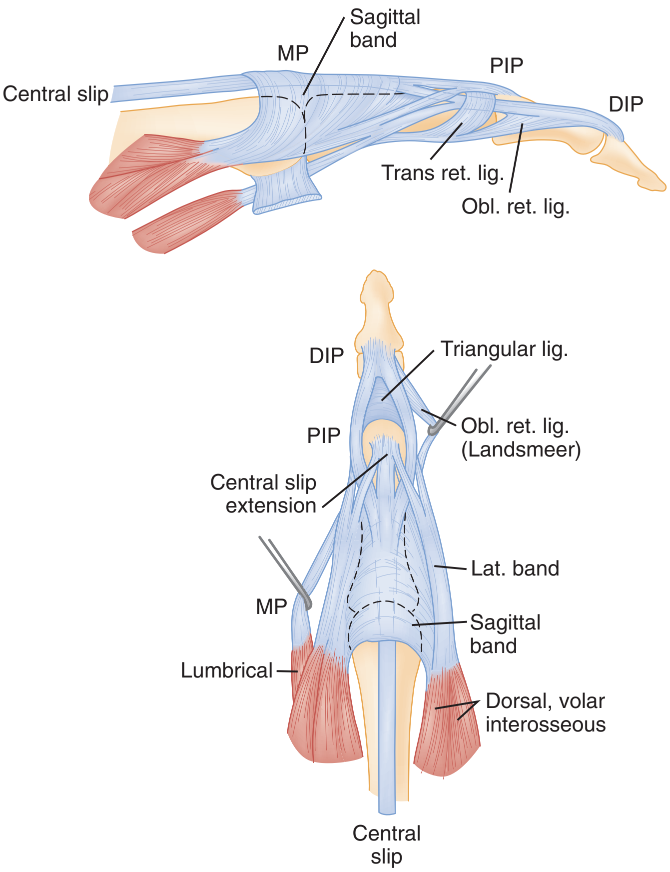

Figure 50-15. The extensor tendon at the metacarpophalangeal *(MP)* joint level is held in place by the transverse lamina or sagittal band, which tethers and centers the extensor tendons over the joint. This sagittal band arises from the volar plate and the intermetacarpal ligaments at the neck of the metacarpals. Any injury to the extensor hood or expansion may result in subluxation or dislocation of the extensor tendon. The intrinsic tendons from the lumbrical and interosseous muscles join the extensor mechanism at approximately the level of the proximal and middle portion of the proximal phalanx and continue distally to the distal interphalangeal *(DIP)* joint of the finger. The extensor mechanism at the proximal interphalangeal *(PIP)* joint is best described as a trifurcation of the extensor tendon into the central slip, which attaches to the dorsal base of the middle phalanx and the two lateral bands. These lateral bands continue distally to insert at the dorsal base of the distal phalanx. The extensor mechanism is maintained in place over the PIP joint by the transverse retinacular ligaments. (From Doyle JR: Extensor tendons-acute injuries. In Green DP [ed]: Operative Hand Surgery. New York, Churchill Livingstone, 1993, p 1928.)

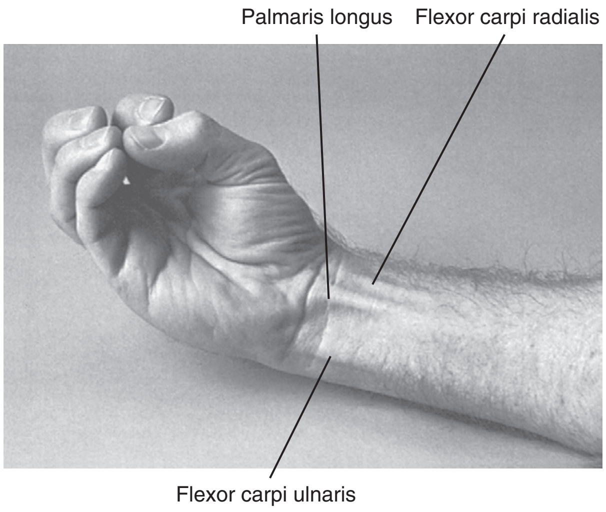

Figure 50-16. Palmaris longus accentuation.

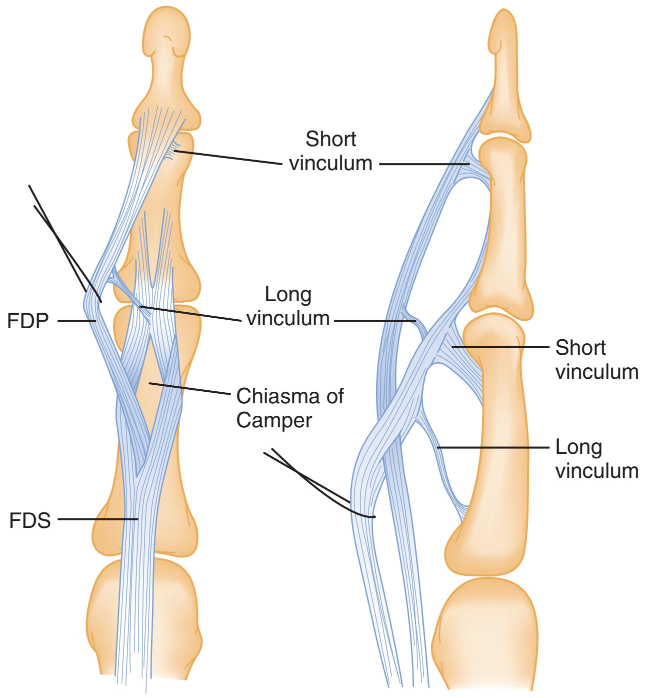

Figure 50-17. Anatomy of flexor digitorum superficialis *(FDS)* and profundus *(FDP)* in the finger. (From Schneider LH: Flexor Tendon Injuries. Boston, Little, Brown, 1985.)

After observation, each muscle-tendon unit is tested with a functional examination. The flexor carpi radialis, palmaris longus, and flexor carpi ulnaris are tested together by having the patient flex the wrist against resistance while the examiner palpates the individual tendons. The tendon of the flexor pollicis longus attaches to the base of the distal phalanx of the thumb and flexes the thumb MCP and IP joints. This tendon is tested by having the patient bend the tip of the thumb against resistance. FDP function can be tested by having the patient flex the distal phalanx of each finger while the PIP is stabilized in extension by the examiner (Fig. 50-19). The FDS is tested individually by asking the patient to flex the PIP joint while the other fingers are held in extension to block the flexion produced by the profundus tendons (Fig. 50-20). This is a subtle but important distinction, because lacerations of the digital creases can easily damage one or more of the tendons or adjacent neurovascular bundles. The FDP is more commonly lacerated in the finger because of its paradoxically superficial position.

If movement against resistance is intact but accompanied by pain or diminished strength, the involved tendon may be partially disrupted. Pathologic nodular swelling of one of the long flexor tendons may result in intermittent catching, or "triggering," on a thickened flexor sheath anterior to the MCP joint. In this condition, known as *trigger finger,* a palpable and sometimes audible snapping can be appreciated when the patient is asked to flex and extend the fingers. On occasion, the patient may need to break the triggering effect by directly palpating the affected joint with the opposite hand.

Synovial Spaces. Bursae are synovial sheaths that cover tendons as they pass through osseofibrous tunnels. They contain synovial fluid and serve two essential functions: They decrease friction during tendon movement, and they help supply nutrients to the

www.ketabpezeshki.com 66485457-66963820

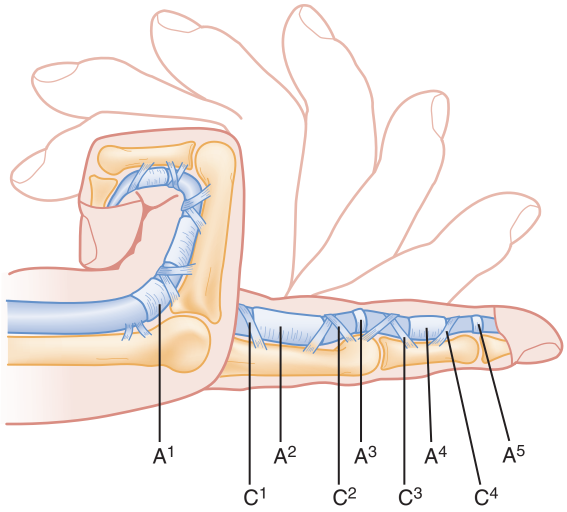

Figure 50-18. The flexor pulley system. The pulleys are thickenings in the fibrous flexor sheath. There are five annular pulleys (transversely oriented fibers) (A^1 to A^5). There are four cruciate pulleys (oblique with some crisscrossing fibers) (C^1 to C^4). (Courtesy Kleinert, Kutz and Associates Hand Care Center.)

Figure 50-19. To test for an intact profundus tendon, the examiner maintains the digit in extension while the patient attempts to flex the terminal phalanx.

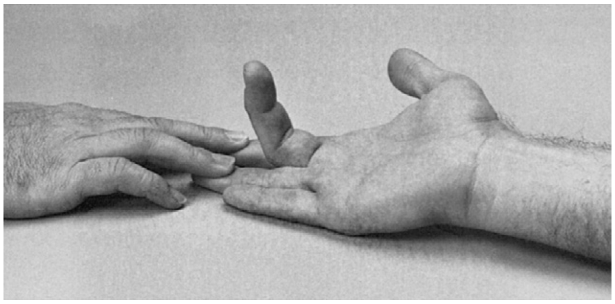

Figure 50-20. Examination to assess function of the flexor digitorum superficialis.

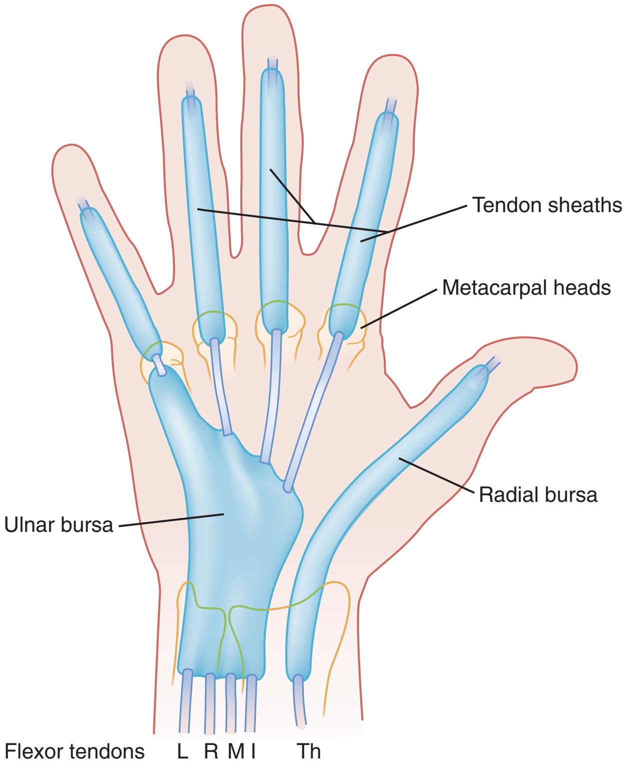

Figure 50-21. Radial and ulnar bursae and their relation to flexor tendons and to each other. *I,* index finger; *L,* little finger; *M,* middle finger; *R,* ring finger; *Th,* thumb. (From Siegel DB, Gelberman RH: Infections of the hand. Orthop Clin North Am 19:779, 1988.)

relatively avascular tendons (Fig. 50-21). These sheaths also can provide pathways for spread of infection. Extensor tendons do not lie within definite sheaths and are afforded a greater resistance to infections. The synovial sheaths of the flexors in the index, middle, and ring fingers are enclosed from their insertion to approximately the level of the distal palmar crease. The sheath of the flexor pollicis longus extends from the tip of the thumb to the proximal volar wrist crease, where it communicates with the radial bursa in the palm and carpal tunnel. Similarly, the synovial sheath of the little finger communicates with the ulnar bursa. Clinical features of flexor tenosynovitis are caused by inflammation and distention of these synovial sheaths. Kanavel[12] described the classic signs: a semiflexed posture of the digit, pain on passive extension of the digit, fusiform swelling, and tenderness of the synovial sheath.

Blood Supply

Arterial System. The hands and the digits have a dual blood supply (Fig. 50-22). The major blood supply to the hand is from the radial and ulnar arteries. The radial artery lies on the anterior aspect of the radius in the distal part of the forearm. It continues around the lateral side of the wrist onto the dorsum of the hand by passing deep to the tendons of the abductor pollicis longus and the extensor pollicis brevis. On entering the palm, the radial artery terminates as the deep palmar arch. The ulnar artery enters the hand anterior to the flexor retinaculum on the radial side of the ulnar nerve and pisiform bone. The artery gives off a deep branch and then continues into the palm as the superficial palmar arch. This complex arterial arch system anastomoses and sends branches to the individual digits and the deep palmar spaces. Because of extensive collateralization, the hand usually survives even if both vessels are transected at the wrist.[13] The circulation of the hand is evaluated by palpation of the radial and ulnar arteries on the volar aspect of the wrist, by assessment of the color and warmth of the skin, and by testing of capillary refill. Because "normal" findings vary among patients, the injured hand should be compared with the unaffected side.

Although Allen's test is an imperfect predictor of vascular compromise, it is commonly used to determine the patency of the arteries supplying the hand and the contributions to the circulation of the hand derived from each of the major vessels. The radial and ulnar arteries are compressed by the examiner at the wrist (Fig. 50-23). The patient opens and closes the hand repeatedly to

www.ketabpezeshki.com 66485457-66963820

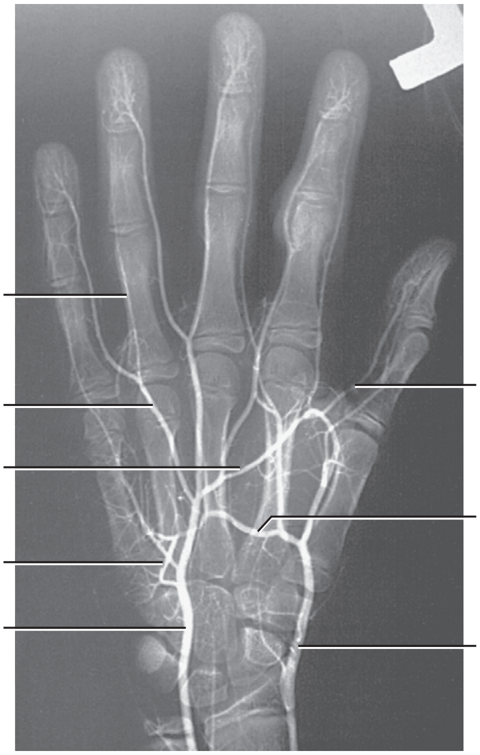

Figure 50-22. Arteriogram of the hand. The ulnar artery is the principal contributor to the superficial palmar arch. (Courtesy Dr. D. Armstrong, Associate Professor of Radiology, University of Toronto, Ontario, Canada.)

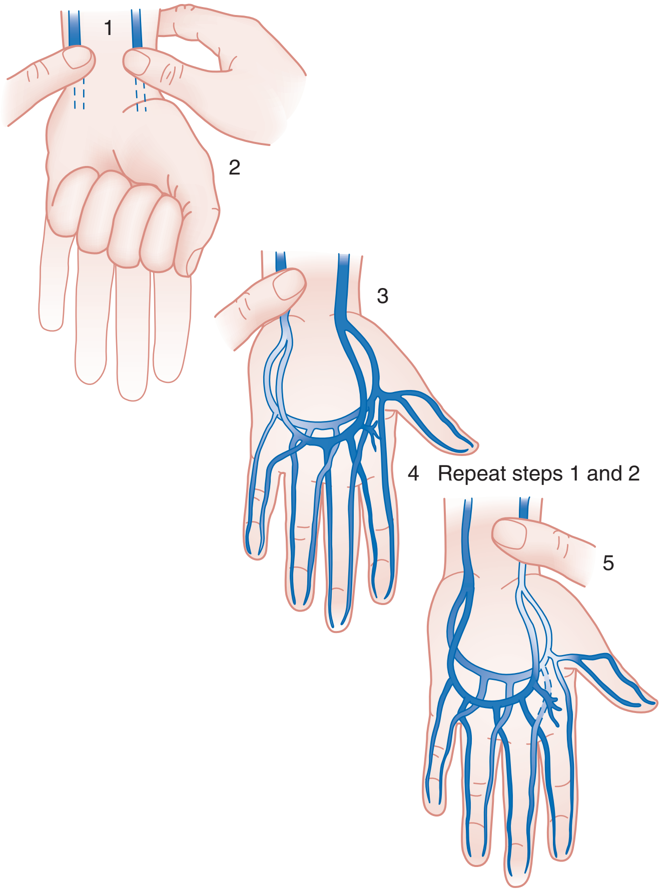

Figure 50-23. Allen's test. (From American Society for Surgery of the Hand: The Hand: Examination and Diagnosis, 3rd ed. New York, Churchill Livingstone, 1990, p 46.)

exsanguinate it and then maintains a relaxed position. The radial artery is released. If the palm and fingers fill immediately with blood, the radial artery is patent, with good collateral flow into the ulnar artery system. To evaluate the ulnar artery, the same steps are repeated, but the ulnar artery is released. This method also can be used on a single digit to help evaluate the patency of each digital artery to that finger. Unilateral digital artery injuries may be well tolerated owing to adequate collateral circulation from the uninjured side. Bilateral digital artery injuries, although rare, tend to have poor outcomes.[13,13a,13b]

Venous and Lymphatic Systems. The veins generally follow the arterial pattern in the deep system. The abundant dorsal, superficial veins are more extensive than the deep system and drain most of the blood from this region. The lymphatic vessels essentially follow the veins, with most lymph flowing into channels in the dorsal subcutaneous space. This vascular anatomy and the laxity of the dorsal skin account for palmar infections causing swelling on the dorsum rather than on the palmar surface of the hand.

Nerve Supply

The nerve supply to the hand comes from the radial, ulnar, and median nerves. All three nerves control movement of the wrist, fingers, and thumb. In the hand, the ulnar and median nerves are mixed motor and sensory nerves, whereas the radial nerve is purely sensory. Each of the three major nerves passes through a muscle in the forearm, and each passes points of potential entrapment en route to the hand.

Motor Innervation. The radial nerve (formed from nerve roots C6 through C8) passes through the supinator muscle and enters the dorsal aspect of the wrist between the radial styloid and Lister's tubercle. At this level, the nerve has a purely sensory function. Its important motor function is to innervate the dorsal extrinsic muscles in the forearm, which extend the wrist and MCP joints and abduct and extend the thumb. No intrinsic muscles in the

www.ketabpezeshki.com 66485457-66963820

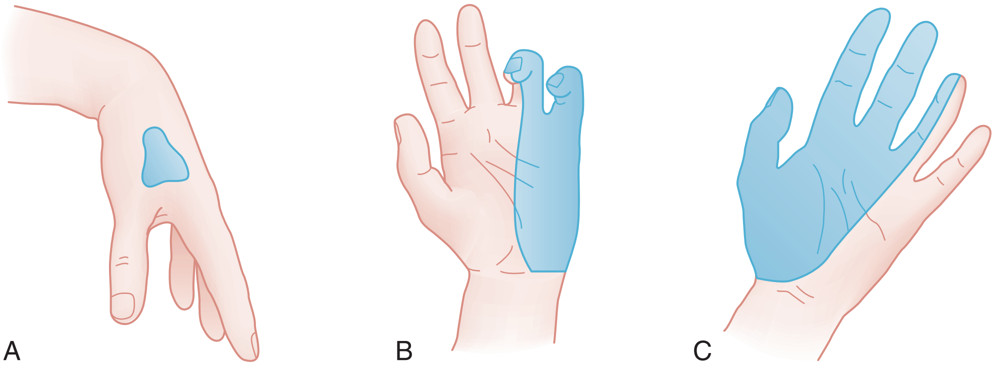

Figure 50-24. Deformities of the hand. **A,** Radial palsy—wristdrop. **B,** Ulnar nerve palsy—*main en griffe* (clawhand). **C,** Median nerve palsy—*main en singe* ("monkey hand"). The shaded areas represent the usual distribution of anesthesia. (From Ellis H: Clinical Anatomy: A Revision and Applied Anatomy for Clinical Students, 7th ed. Oxford, UK, Blackwell Scientific, 1983.)

hand are innervated by the radial nerve. Motor function in this nerve is tested by having the patient extend the wrist against resistance. Proximal injury to the radial nerve causes a condition known as *wristdrop:* The fingers are held in flexion at the MCP joints, and the thumb is adducted (Fig. 50-24A).

The ulnar nerve (C7, C8, and T1) passes through the flexor carpi ulnaris muscle in the forearm and lies ulnar to the artery and superficial to the flexor retinaculum. It enters the hand at the wrist through the ulnar tunnel, or Guyon's canal. The ulnar nerve innervates the hypothenar muscles, the seven interosseous muscles, the lumbrical muscles to the ring and little fingers, and the adductor pollicis. Innervation of the flexor pollicis brevis is variable. In the forearm, the flexor carpi ulnaris and the ulnar half of the FDP also are innervated by the ulnar nerve. Loss of motor function of the ulnar nerve results in inability to pinch a piece of paper tightly between the thumb and the index finger. A late characteristic of distal ulnar damage is Duchenne's sign, manifested by clawing of the ring and little fingers (see Fig. 50-24B). The ring and little fingers are hyperextended at the MCP joints by the extensor digitorum communis (radial nerve) and flexed at the IP joints by the FDP (intact proximal ulnar nerve). In addition, the interosseous and hypothenar muscles are atrophied.

The median nerve enters the forearm through the pronator teres muscle. At that level, it innervates that muscle, the flexor carpi radialis, the FDS, the radial part of the FDP, the flexor pollicis longus, and the pronator quadratus. The branch of the median nerve that innervates the last three muscles is called the *anterior interosseous nerve.* The median nerve enters the hand through the carpal tunnel accompanied by the nine extrinsic flexor tendons of the digits. The thenar motor branch (recurrent median nerve) innervates the abductor pollicis brevis, the opponens pollicis variably, and the flexor pollicis brevis. Common digital branches innervate the lumbrical muscles to the index and long fingers. Injury to this nerve occurs most commonly at the level of the wrist, by laceration or by compression in the carpal tunnel. Motor function is tested by having the patient appose the thumb to the index digit. Injury to the median nerve in the upper forearm or at the elbow usually results in weakness or absence of flexion of the index finger distal phalanx, the middle phalanx, and the thumb and weakness of thumb abduction and opposition. With passage of time, the muscles of the thenar eminence atrophy, leaving the hand with a flattened and "apelike" appearance (see Fig. 50-24C).

Sensory Innervation. The typical distribution of the sensory nerves to the hand is shown in Figure 50-25. Because some overlap occurs between various sensory nerves, it is preferable to test sensation in the areas least likely to have dual innervation. The anatomic area of least ulnar variation and overlap is the volar tip of the little finger. The median nerve exclusively innervates the volar tip of the index finger. The dorsal first web space is entirely within the radial nerve distribution.

Several methods exist to assess sensation. Two-point discrimination is one such method, although both the accuracy and objectivity of this test have been called into question.[14] An uninjured hand is able to distinguish two points that are 2 to 5 mm apart at the fingertips and 7 to 10 mm apart at the base of the palm. The dorsum of the hand is the least sensitive region, with a normal threshold at 7 to 12 mm. Two-point threshold distances wider than these ranges indicate impaired sensory function.[14] The threshold and two-point discrimination tests may be of limited value in children, patients with heavily calloused fingertips, uncooperative patients, comatose patients, patients in severe pain, or suspected malingerers. In such patients, submerging the hand in water and observing the skin for the development of wrinkles has been offered as a way to diagnose nerve impairment because denervated skin will not wrinkle.[15]

Fingertip

The fingertip generally is defined as the area distal to the insertion of the flexor profundus and extensor tendons (Fig. 50-26). The

www.ketabpezeshki.com 66485457-66963820

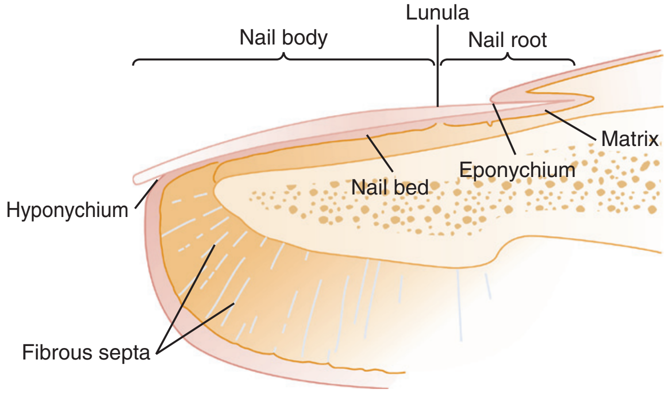

Figure 50-26. Sagittal section of the distal finger, showing structures of the fingertip. (From Siegel DB, Gelberman RH: Infections of the hand. Orthop Clin North Am 19:779, 1988.)

pulp is the tissue of the fingertip between the volar skin and the distal phalangeal bone. The fingertip is well padded by adipose tissue and is covered by highly innervated skin that is tethered to the distal phalanx by a series of fibrosepta. The dorsal skin is thinner and less vascularized than the volar skin. Sensation is supplied by nerves that travel with arteries bilaterally along the radial and ulnar aspects of the fingers. The arteries branch to form volar anastomoses or arches similar to those in the palm. Dorsal branches supply the nail bed and matrix.

Nail

The nail (or nail plate) consists of compacted scales that originate from cornified epithelial cells. The proximal part of the nail is called the *root;* it emerges from a groove in the skin to form the body of the nail, which is exposed. The root of the nail is covered by a fold in the skin called the *proximal nail fold.* A small portion of the epidermis of the nail fold extends out over the proximal body of the nail to form the cuticle, or *eponychium.* The floor of the nail plate or nail bed is composed of tissue known as the *nail matrix.* The distal skin of the nail bed complex is called the *hyponychium.* The skin overlying the nail laterally is called the *perionychium.* The semicircular white crescent region near the nail fold is called the *lunula.*

The nail bed complex is important in providing additional stabilization of the palmar soft tissues against compression and shear forces. The nail grows from the nail matrix along the nail bed and is firmly adherent to the bed. It is now believed that the entire nail bed is active in the generation and migration of the nail. As new nail forms, it glides forward over the nail bed at a rate of approximately 0.5 to 1.2 mm per week (toenails grow much more slowly). The nail itself is a hard, firm, and relatively translucent structure; the underlying vascular tissue showing through gives the nail its pink appearance. A smooth nail bed is essential to normal function. If the nail bed sustains injury that is not repaired accurately, granulation tissue forms scar that impedes normal nail production and growth. The result may be a split or absent nail that is cosmetically unappealing and sometimes functionally debilitating.[16]

CLINICAL FEATURES: SIGNS AND SYMPTOMS

The initial evaluation of an acutely injured hand is crucial because it affords the best opportunity for accurate assessment of the extent of damage and for restoration of altered anatomy.[17] Evaluation of any hand injury should begin by obtaining the historical

facts of the patient's age, occupation, hand dominance, and previous hand impairment or injury. In traumatic injuries, elapsed time since the injury, mechanism of injury, posture of the hand at the time of injury, and treatment before arrival in the ED all are useful data. In nontraumatic problems, pain, swelling, sensory change, contracture, timing of symptoms, presence of similar symptoms in other extremities, aggravating or alleviating factors, and functional impairment are useful historical points. A review of the medical history and a review of systems complete the evaluation.

After a detailed history is taken, the entire extremity should be exposed and evaluated when the hand is examined. A system of priorities, based primarily on threat to ultimate function, should direct the sequence of the examination. In order of priority, the examination includes evaluation of vascular and neurologic integrity, skin cover, skeletal stability, and joint and tendon function (Box 50-1). The general appearance of the hand should be noted, with focus on its color, presence of swelling or edema, and any abnormal posture or position. In traumatic injuries, the precise area of maximal tenderness should be localized. Rotational, angular, and shortening deformities should be noted with regard to direction and extent. Angular deformity may be seen best with the fingers in full extension. Rotational deformity is best observed during digital flexion. Digital or wrist block anesthesia may be helpful in some cases to accurately assess fracture deformity and stability during digital motion and, if necessary, stress testing. Open wounds should be assessed with regard to location, relationship to skin creases, direction and viability of skin flaps, extent of skin loss, degree of contamination of the wound, and extent of

www.ketabpezeshki.com 66485457-66963820

soft tissue injury. The examiner should have good light, adequate exposure, and a nearly bloodless field for a thorough evaluation. The complete examination also may require an evaluation of active shoulder motion, elbow motion, and pronation and supination of the forearm and assessment of the contralateral hand.

DIAGNOSTIC STRATEGIES: RADIOLOGY

Despite the development of numerous new and sophisticated imaging techniques, plain radiography remains the most important imaging modality for the hand and wrist. The standard radiographic series of the hand should include a posteroanterior, a true lateral, and an oblique projection (Fig. 50-27). With correct positioning, the bones do not overlap on the film, allowing complete evaluation of each area for visualization of fractures, subluxation, dislocation, deformities, and retained radiopaque foreign bodies.[18] On a hand series, the wrist is not properly positioned for radiographic examination, and vice versa; if the patient has injuries to the hand and wrist, separate radiographic series should be obtained.

For an adequate posteroanterior view, the forearm and hand should be fully pronated so that the palm rests flat on the film. This view forms the basis for all assessments but is poor at showing fractures of the articular surface of the metacarpal head. The lateral view normally is a radioulnar projection and is made by positioning the palm and forearm at 90 degrees to the film with the fingers splayed. This view is essential to show displacement of

Figure 50-27. Normal hand radiographs. **A,** Anteroposterior view. **B,** Lateral view. **C,** Oblique view. The hand is routinely examined in three different planes to identify fractures that may escape detection on the usual anteroposterior and lateral views because of overlapping bony structures. (From Rosen P, et al: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1992, p 179.)

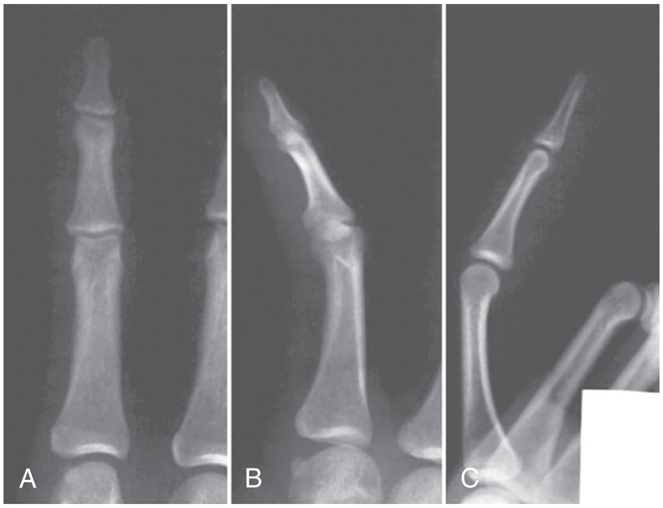

Figure 50-28. Normal radiographic appearance of fingers of three different patients.

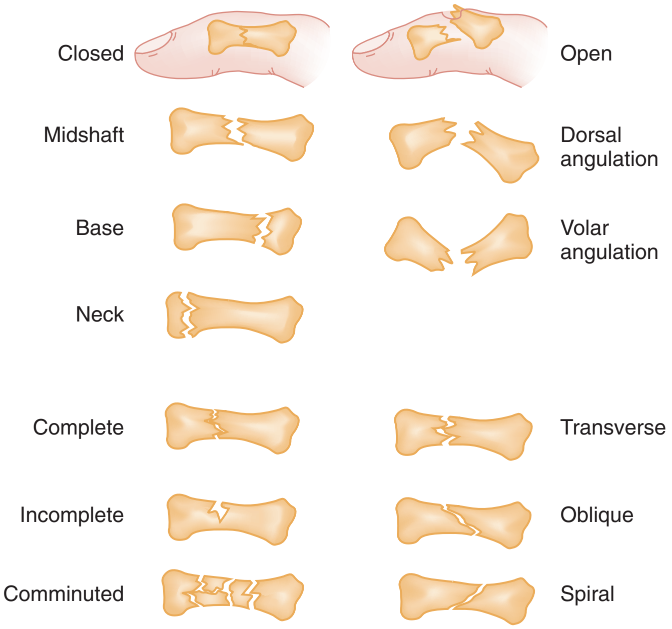

Figure 50-29. Fracture terminology. (From Idler RS, et al [eds]: The Hand: Examination and Diagnosis, 3rd ed. New York, American Society for Surgery of the Hand, 1990, p 64.)

fracture fragments and joint dislocations. If the projection is not a true lateral view, joint dislocation, avulsion fractures, or fractures through the articular surface of the base of the phalanx may be overlooked. The oblique view is obtained with the hand and forearm pronated at 45 degrees to the film. It is particularly useful for assessing dislocation of the MCP and CMC joints and fractures at the base of the metacarpal bones. When injury is confined to the distal end of a single digit, radiologic evaluation should be limited to that digit, but the same projections are used (Fig. 50-28).

Special views are used to diagnose specific injuries. The standard views of the hand do not give true posteroanterior and lateral projections of the thumb because the plane of the thumb is at 90 degrees to that of the fingers. Separate posteroanterior and lateral views of the thumb should be requested. The posteroanterior projection of the thumb is obtained with the hand and forearm hyperpronated so that the dorsal surface of the thumb and the thumb metacarpal rests flat on the film. The lateral view is obtained by pronating the hand and forearm to allow the lateral surface of the thumb to lie on the film. Stress views are used most often to rule out ligamentous injury to the first MCP joint. Localized widening of the joint space or subluxation may indicate a significant collateral ligament injury. Plain radiographs taken in multiple projections can help detect and localize soft tissue foreign bodies. Whether an object can be visualized will depend on its composition, configuration, size, and orientation. Many foreign bodies encountered in the ED, including almost all glass, are more dense than soft tissue and can be readily seen on plain radiographs.[19] Plastic and wood foreign bodies are notable exceptions, with many of these objects being radiolucent.

MECHANISMS OF INJURY AND MANAGEMENT

Trauma

The bones of the hand are the most commonly fractured bones in the body. Radiologic evaluation of significant hand injuries is mandatory. Any hand injury that causes swelling should be evaluated radiographically with a minimum of three views. Although the classification of hand fractures is difficult and at times confusing, it generally is done according to the nature and site of the fracture line and whether the fracture is open or closed (Fig. 50-29).

A fracture is unstable if it cannot be reduced or maintained in an anatomic or near-anatomic position without fixation when the hand is placed in the "safe" or functional position. The four principal determinants of fracture stability or instability are (1) fracture configuration, (2) integrity of the periosteal sleeve and surrounding soft tissues, (3) muscle balance or imbalance, and (4) external forces.

In general, transverse fractures have a stable configuration. Spiral, oblique, and comminuted fractures are unstable. The degree of displacement also is an indicator of potential fracture instability. Fractures of inherently unstable configuration may be stable if they are nondisplaced or only minimally displaced because the periosteum is undamaged or minimally disrupted. Displacement is defined by the deformity it creates and can result in rotation, angulation, shortening, or a combination of these fractures. Although shortening has an adverse effect on muscle tension, the hand accommodates more easily to this component of deformity than to others.[18]

Definitive management of many hand fractures is controversial and beyond the scope of this discussion. The emphasis here is on appropriate initial interventions, including proper splinting techniques to minimize morbidity, and recognition of which fractures may require operative fixation and their potential complications. Most closed injuries may be treated initially in the ED. Most open, intra-articular, periarticular, and unstable fractures require operative management by a hand surgeon.

Distal Phalanx Fractures

Pathophysiology and Clinical Features

Fractures of the distal phalanx are the most common fractures of the hand. They occur most often as a result of crush or shearing forces, usually as a sports-related injury in children and adolescents, industrial accidents in adults, or accidental falls in elderly persons.[20] Distal phalangeal fractures are classified as extra-articular fractures (longitudinal, transverse, and comminuted) or intra-articular fractures. The most common location for these

www.ketabpezeshki.com 66485457-66963820

Figure 50-30. Tuft fracture of the distal phalanx of the thumb, anteroposterior view. This radiograph reveals the comminuted displaced fracture fragments and some radiopaque foreign material on the substance of the nail. (From Rosen P, et al: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1992, p 180.)

fractures is the distal tuft (Fig. 50-30). Because the mechanism of injury is usually direct trauma, tuft fractures often are comminuted and usually are associated with soft tissue injury to the nail, nail bed, and nail matrix.[21] Supporting fibrous septa that radiate from the bone to the skin prevent displacement of fracture fragments and act to contain soft tissue swelling, contributing to the severe pain that can accompany these fractures. Examination typically reveals tenderness and swelling over the distal phalanx, including the pulp.

Fractures at the base of the distal phalanx may be associated with tendon avulsion. The flexor profundus tendon attaches to the volar aspect of the index, middle, ring, and little fingers, and the terminal slip of the extensor tendon attaches on the dorsal surface of the distal phalanx. In the distal phalanx of the thumb, the flexor pollicis longus inserts on the volar base, and the extensor pollicis longus inserts on the dorsal base. These tendons can avulse when subjected to excessive stress. Clinically, loss of function is evident, and small avulsion fractures along the dorsal or volar surface may be seen on radiographs. These fractures are considered intra-articular, and their management is as for other tendon injuries.

Management

Treatment of most fractures of the distal phalanges is directed toward the accompanying soft tissue injury. Closed tuft fractures need only symptomatic treatment with elevation (to reduce swelling) and analgesics. Fracture immobilization is rarely necessary; however, a short volar splint or hairpin splint (Fig. 50-31) is recommended for 2 to 3 days to protect the tip of the finger from further trauma and allow swelling without constriction. Immobilization should not include the PIP joint. Transverse shaft fractures with angulation or displacement may be irreducible because of interposition of soft tissue. Closed reduction may be attempted

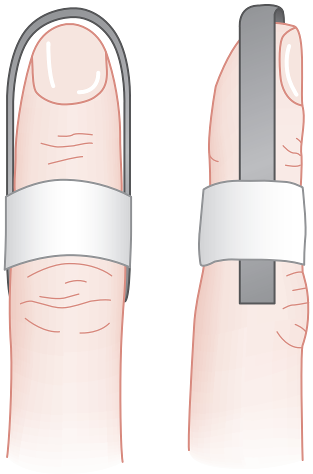

Figure 50-31. The hairpin splint used for distal phalangeal fractures. (From Simon RR, Koenigsknecht SJ: The hand. In Simon RR [ed]: Emergency Orthopedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1995, p 59.)

with dorsal traction on the distal fragment followed by immobilization with a volar splint and repeat radiographs for documentation of position. If this approach is unsuccessful, referral to a hand surgeon is indicated for Kirschner wire fixation.[21]

Distal phalangeal fractures associated with nail bed laceration are considered open fractures. This may be obvious if the nail has been avulsed or torn, but recognition of nail bed laceration is more difficult in closed tuft fractures with an intact nail despite presence of a subungual hematoma. Subungual hematomas often are associated with occult lacerations of the nail bed, and in such cases removal of the nail for accurate assessment and laceration repair uncommonly may be required.

Complications

Distal phalanx fractures generally are uncomplicated; however, distal phalanx fractures that appear innocuous can result in prolonged morbidity, especially if associated with soft tissue crush injury. In a long-term follow-up series, DaCruz and associates[22] showed that at 6 months 31% of tuft fractures had not healed radiographically and 70% of all patients had bothersome symptoms, including numbness, hyperesthesia, and cold sensitivity. Trauma to the nail bed may result in abnormal nail growth despite exact tissue approximation. Failure to recognize and extricate an entrapped nail bed in the fracture site may result in nonunion of the fracture. Osteomyelitis from open fractures is a rare but potentially serious complication.

Proximal and Middle Phalangeal Fractures

Pathophysiology and Clinical Features

Because the anatomy, mechanism of injury, and treatment for proximal and middle phalangeal fractures are similar, these fractures are discussed together. The proximal phalanx has no tendinous attachments. Fractures in this region have a typical volar angulation resulting from forces exerted from the extensors and the interosseous muscles. The middle phalanx has two important insertions. The tendon of the FDS divides and inserts along nearly the entire volar surface of the phalanx, and the extensor tendon inserts on the proximal dorsal base of the middle phalanx. Because of this alignment, fractures at the base of the middle phalanx usually result in dorsal angulation, and fractures at the neck of the

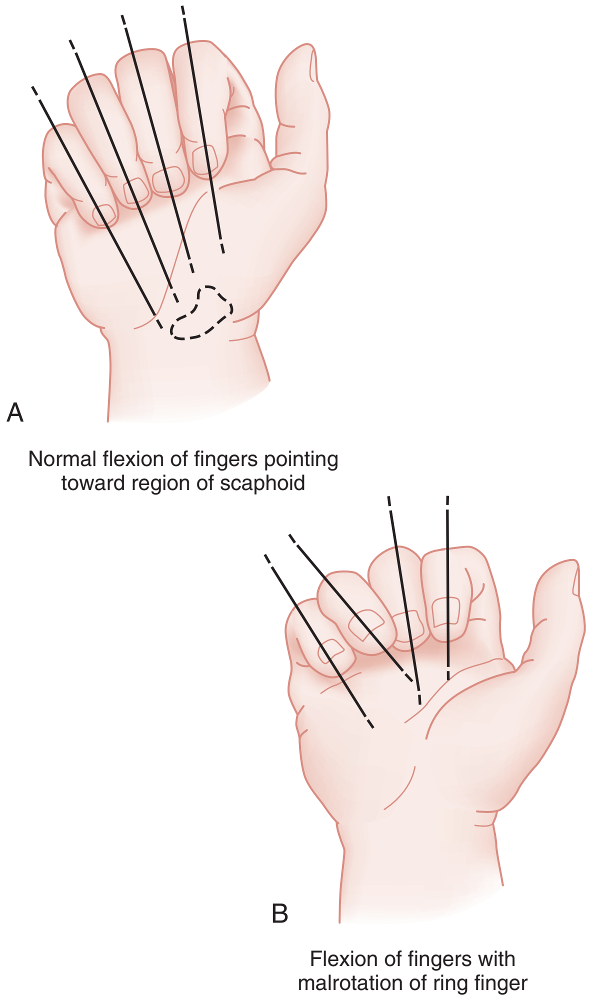

Figure 50-32. Any malrotation of a metacarpal or phalangeal fracture should be corrected. **A,** Normally all fingers point toward the region of the scaphoid when a fist is made. **B,** Malrotation at fracture causes the affected finger to deviate. (From Jobe MT, Calandruccio JH: Fractures, dislocations and ligamentous injuries. In Canale ST [ed]: Campbell's Operative Orthopedics, 10th ed. St. Louis, Mosby, 2003, p 3484.)

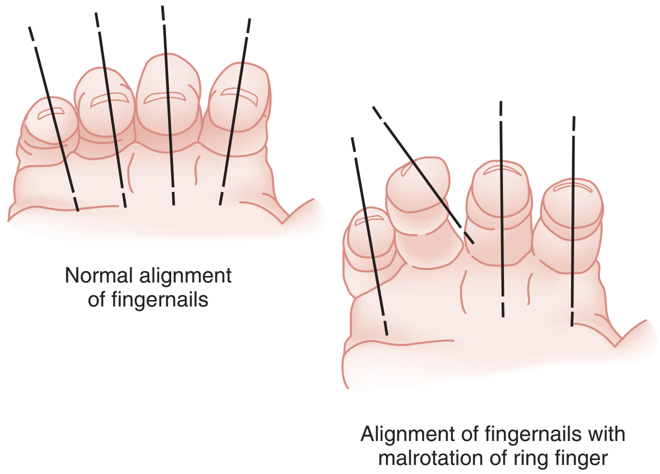

Figure 50-33. Observing the plane of the fingernails helps detect any malrotation at the fracture. (From Jobe MT, Calandruccio JH: Fractures, dislocations and ligamentous injuries. In Canale ST [ed]: Campbell's Operative Orthopedics, 10th ed. St. Louis, Mosby, 2003, p 3484.)

middle phalanx usually result in volar angulation.[23] The mechanism of injury often determines the nature of the fracture; a direct blow is more likely to cause a transverse or comminuted fracture, whereas a twisting injury more often results in an oblique or spiral fracture. Associated injuries may include contusion or transection of digital nerves, vascular disruption, and tendon rupture.

Intra-articular fractures include condylar fractures; comminuted fractures; dorsal, volar, or lateral base fractures; fracture-dislocations; and shaft fractures involving the joint. Extra-articular fractures involve the neck, shaft, or base of the phalanx. Although most phalangeal fractures may be easily seen, condylar fractures and displaced neck fractures are not always apparent on anteroposterior radiographs; oblique views may be needed to identify them.[24] Rotational deformities are difficult to determine by radiologic study but may appear on the lateral view as discrepancies in the diameter of the shaft at the fracture site.

Skeletal alignment can be assessed radiographically, but rotational alignment should be judged clinically by the relationship of the finger to adjacent normal fingers (Fig. 50-32). Symmetrical flexion of adjacent injured and normal fingers at their MCP and PIP joints is the best possible guide to accurate rotational alignment of the injured segment.[23] Normally, all of the fingers of the closed fist except the thumb should point to the scaphoid. Alternatively, when the fingers are loosely flexed, the nails of opposing digits should lie in the same parallel plane (Fig. 50-33). The uninjured hand should be used for comparison.

Management

Similar to metacarpal fractures, phalangeal fractures require precise anatomic alignment to ensure a good result because of the intimate relationship of the flexor and extensor tendons to the phalanx.[23] Appropriate treatment selection depends on accurate assessment of fracture stability. The angle of the fracture is an important factor in determining this stability. Transverse fractures usually are stable, whereas oblique fractures are inherently unstable. It also is important to ascertain whether the fracture has been impacted or displaced and what deforming forces are acting on it. If there is any question of the fracture's stability, the digit should be anesthetized, and stress should be applied. Reduction of phalangeal fractures usually is not necessary because most are stable and nondisplaced.[17] Patients with such fractures should be started on early protected motion as soon as pain subsides (within the first 3 to 5 days). Protection is provided by taping the injured digit to an adjacent, larger normal finger proximally, a form of *dynamic splinting.* This technique, known as "buddy-taping," encourages the patient to move the finger and use the hand as normally as possible while the fracture heals (Fig. 50-34).

If the fracture is displaced or unstable, it is not suitable for dynamic splinting. In general, treatment depends on the type of trauma and the ability to achieve a stable reduction. Phalangeal fractures that are satisfactorily managed by closed reduction can be immobilized by several methods. In such cases it is advisable to immobilize the wrist and the injured finger. Specific types of immobilization include circular cast, the Böhler method of incorporating a cast with an outrigger, gutter splints, and anterior and posterior splints (Fig. 50-35). The period of immobilization of phalangeal fractures should not exceed 3 weeks, to prevent stiffness and to minimize disability. In addition to temporary immobilization, ED management includes ice for comfort, elevation, analgesics, and referral for follow-up care. Repeat radiographs in 7 to 10 days are recommended to ensure that no delayed displacement has occurred.

Unstable fractures that cannot be reduced by closed manipulation and maintained with external splinting require internal fixation. Midshaft transverse fractures tend not to be amenable to closed reduction; similarly, spiral oblique fractures and

www.ketabpezeshki.com 66485457-66963820

intra-articular fractures are inherently unstable and require surgical fixation if a significant portion of the articular surface is involved.[25] Intra-articular fractures of the proximal metaphysis of the middle phalanx that have extreme comminution may require treatment in static or dynamic traction or external fixation with or without ancillary Kirschner wire fixation.[25]

Complications

Malunion is the most common bony complication of phalangeal fractures and may result from malrotation, volar or lateral angulation, or shortening. Malrotation usually is seen after oblique or spiral fractures of the proximal and middle phalanges and may require osteotomy through the phalanx or metacarpal for correction. Volar angulation of proximal phalangeal fractures greater than 25 to 30 degrees results in pseudoclawing. This deformity makes use of the hand awkward and is esthetically unacceptable. Other potential complications include diminished motion resulting from tendon adhesions and stiffness of the PIP joint after intra-articular fractures with incongruity.[23]

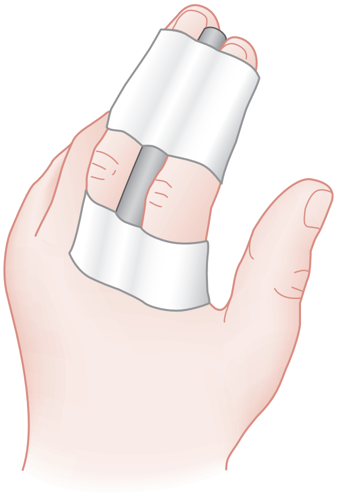

Figure 50-34. The injured finger is splinted to the adjacent normal finger. This splint provides support for the injured digit while permitting motion of the metacarpophalangeal joint and some motion at the interphalangeal joint. A piece of felt cut to the proper size is inserted between the fingers, and the two digits are taped together as shown. (From Simon RR, Koenigsknecht SJ: The hand. In Simon RR [ed]: Emergency Orthopedics: The Extremities, 3rd ed. Norwalk, Conn, Appleton & Lange, 1995, p 518.)

Metacarpal Fractures

Metacarpal fractures generally are divided into two groups: fractures involving the thumb metacarpal and fractures involving metacarpals of the index, middle, ring, and little fingers. This distinction is based on the fact that the base of the thumb metacarpal is biomechanically distinct from the remaining metacarpals because of its high degree of mobility. For this reason, these two groups are discussed separately.

Metacarpal Fractures of the Index, Middle, Ring, and Little Fingers

The hand can adjust functionally to dorsal angulation in the metacarpal equal to its motion at the CMC joint, plus 10 to 15 degrees in some patients. Because the index and middle fingers are immobile at their CMC joints, they may accommodate only 10 to 15 degrees of dorsal angulation. The ring finger usually has 20 to 30 degrees of mobility at its CMC joint and may accommodate 40 to 45 degrees of dorsal angulation. The small finger generally has 30 to 50 degrees of motion at its base and may accommodate 50 to 70 degrees of dorsal angulation. Finger metacarpals may tolerate 10 to 15 degrees of lateral angulation and 3 to 4 mm of shortening. Rotational deformity, most commonly seen in spiral and oblique fractures, is poorly tolerated. A small amount of rotational deformity can translate into a substantial digital overlap when the fingers are closed to form a fist. Just 10 degrees of malrotation may cause as much as 2 cm of overlapping (scissoring) of the fingers during flexion.[17] Surgical intervention is indicated with 2 to 3 mm of shortening, 1 mm of articular surface step-off, greater than 25% articular involvement, or any degree of malrotation.[23]

Metacarpal Head Fractures

Pathophysiology. Fractures of the metacarpal head are rare. They usually occur as a result of direct trauma or crush injury and typically are comminuted.[21] These fractures occur distal to the attachment of the collateral ligaments. Physical examination reveals tenderness and swelling over the involved MCP joint. Pain is increased if axial compression is applied along the extended digit. The presence of lacerations over the metacarpal heads is significant and suggests the possibility of an open fracture potentially caused by human bite injury.

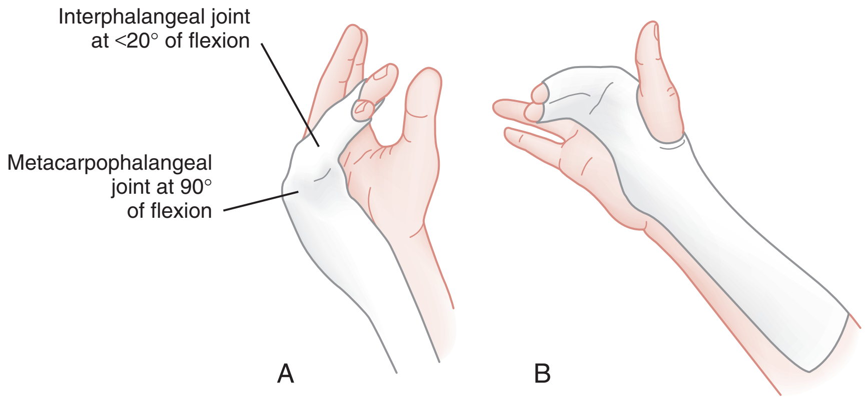

Figure 50-35. Gutter splints are used for the treatment of phalangeal and metacarpal fractures. **A,** Fractures of the ring and little fingers are immobilized in an ulnar gutter splint. **B,** Fractures involving the index finger and the long finger are immobilized in a radial splint. The splint is made with plaster sheets cut to the proper size. The measurement should be from the tip of the finger to a point two thirds of the way up the forearm. (From Simon RR, Koenigsknecht SJ: The hand. In Simon RR [ed]: Emergency Orthopedics: The Extremities, 3rd ed. Norwalk, Conn, Appleton & Lange, 1995, p 519.)

www.ketabpezeshki.com 66485457-66963820

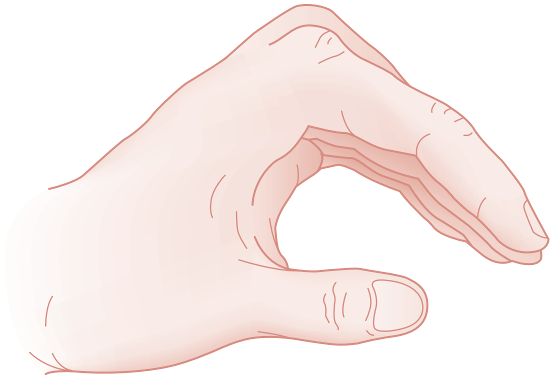

Figure 50-36. The "safe" position described by James. (Adapted from Stern PJ: Fractures of the metacarpals and phalanges. In Green DP [ed]: Green's Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999.)

Diagnostic Strategies: Radiology. Although routine radiographic imaging of the injured hand reveals most fractures, the metacarpal heads can be difficult to assess because of overlap on the lateral view. In such cases in which clinical suspicion of a fracture exists and the initial radiographic appearance is normal, the Brewerton "ball-catcher's" view may be helpful.[26] This view is obtained with the digits in 65 degrees of flexion at the MCP joints and the x-ray beam angled 15 degrees radially, projecting the metacarpal heads in profile. Occasionally, computed tomography also may be required to evaluate accurately the degree of displacement of intra-articular fractures at the MCP level.

Management. Emergency management of closed metacarpal head fractures consists of elevation, ice for comfort, analgesics, and immobilization of the hand in the "safe" or functional position, which balances the forces of the intrinsic muscles. In this position, shown in Figure 50-36, the wrist is extended 20 degrees, the MCP joints are flexed to 90 degrees, and the PIP and the DIP joints are extended. Referral to a hand surgeon for management and follow-up evaluation is required in all cases. Because these are intra-articular fractures, displacement by more than 1 to 2 mm predisposes the patient to a poor result; however, little consensus has been reached regarding optimal definitive treatment.[27]

Lacerations or puncture wounds over the dorsum of the MCP joint associated with a metacarpal head fracture should be considered open until proven otherwise. Such injuries often are caused by a clenched-fist injury and are highly contaminated wounds. Emergent consultation with a hand surgeon for operative débridement and irrigation is recommended. Prophylactic coverage with a cephalosporin is routinely recommended, although patients with highly contaminated wounds should receive penicillin with a β-lactamase inhibitor and an aminoglycoside.[28] Several studies have found preoperative wound cultures to be of no value in predicting the risk of infection or identifying the likely pathogen, and some clinicians have abandoned their use.[29,30]

Complications. Metacarpal head fractures may be associated with debilitating hand complications, including avascular necrosis, rotational malalignment, interosseous muscle fibrosis, extensor tendon injury or fibrosis, and chronic stiffness of the MCP joint. Many of these fractures also may require late arthroplasty.[21]

Metacarpal Neck Fractures

Pathophysiology. Fractures of the metacarpal neck are among the most common fractures in the hand. The mechanism of injury is a direct impaction force (e.g., a punch with a closed fist). A *boxer's fracture* is a fracture of the neck of the little finger metacarpal (Fig. 50-37). Most metacarpal neck fractures have a typical apex dorsal angulation. They are inherently unstable because of the deforming muscle forces and frequent comminution of the volar cortex. Management generally is difficult because of this instability and the difficulty in maintaining reduction.

Figure 50-37. Boxer's fracture *(arrow)*. (From Harris JH Jr, et al: The Radiology of Emergency Medicine. Baltimore, Williams & Wilkins, 1993, p 444.)

Management. For treatment purposes, metacarpal neck fractures are divided into two groups: fractures involving the ring and little finger metacarpals and fractures involving the index and long finger metacarpals. There is considerably more mobility of the metacarpals of the ring and little fingers compared with the index and long fingers. This greater mobility makes them more prone to fracture, and the relative immobility of the index and long finger metacarpals increases the need for accurate alignment after reduction. In general, less than 15 degrees is allowed in the index and long finger metacarpals; in the ring and little finger metacarpals, 35 degrees and 45 degrees of angulation, respectively, are allowed. Any rotational malalignment should be completely corrected.

Nondisplaced ring and little finger metacarpal fractures without angulation deformity can be treated initially with ice, limb elevation, analgesia, and immobilization in a gutter splint. Nondisplaced, nonangulated metacarpal fractures of the index and long finger metacarpals are treated similarly. The splint should be in standard position of function and extend from below the elbow up to, but not including, the PIP joint. In general, it is recommended to begin PIP and DIP motion without delay. Protected MCP motion can begin in 3 to 4 weeks.[21] For isolated fractures of the little finger metacarpal neck, some clinicians advocate immediate mobilization of fractures regardless of the degree of angulation. Results with this approach include excellent function, with only minor cosmetic deformity, and early return to work. Early follow-up evaluation is advised to exclude residual angulation, rotational deformity, and delayed displacement.[31]

Reduction of ring and little finger metacarpal neck fractures with significant angulation or deformity may be attempted in the

www.ketabpezeshki.com 66485457-66963820

Figure 50-38. The 90-90 method for metacarpal neck fracture reduction.

Figure 50-39. This radiograph shows the typical dorsal angulation of fractures of the metacarpal shafts. These fractures usually are the result of a direct blow and generally angulate dorsally because of the volar force exerted by the interosseous muscles. (From Green DP, Rowland SA: Fractures and dislocations in the hand. In Rockwood CA Jr, Green DP [eds]: Fractures in Adults. Philadelphia, JB Lippincott, 1991, p 490.)

ED. After appropriate anesthesia is obtained, usually with a hematoma block or an ulnar nerve block, traction is applied on the metacarpal to disimpact the fracture. The MCP joints and IP joints are flexed at 90 degrees, and simultaneous pressure is applied in a volar direction over the metacarpal shaft and in a dorsal direction over the flexed PIP joint (Fig. 50-38). This maneuver is termed the *90-90 method* and should complete reduction. A gutter splint in position of function should be applied. Postreduction radiographs should be obtained immediately and after 1 week to ensure that reduction has not been lost. If closed reduction cannot be achieved or maintained, pin fixation by a hand surgeon is necessary, and early referral is indicated.

Displaced or angulated index or long finger metacarpal neck fractures commonly require anatomic reduction and surgical fixation. ED management consists of ice, limb elevation, and the application of a volar splint. Prompt referral to a hand surgeon is necessary.

Complications. Metacarpal neck fractures may have an associated rotational component that can impair function and result in overlapping of the affected finger over an adjacent finger. If excessive angulation is not corrected, the patient may experience forced hyperextension of the MCP joint and flexion of the PIP joint when extending the finger and pain when tightly grasping objects. Other complications include extensor tendon injury and collateral ligament damage. Nonunion is rare after closed metacarpal fractures.

Metacarpal Shaft Fractures

Pathophysiology. There are three types of metacarpal shaft fractures: transverse, oblique or spiral, and comminuted. Transverse and comminuted fractures usually result from a direct blow and commonly exhibit dorsal angulation (Fig. 50-39). Indirect trauma or rotational torque applied to the finger may result in a spiral shaft fracture. These fracture fragments tend to shorten and rotate rather than angulate.

Management. Metacarpal shaft fractures are treated differently than fractures involving the neck because rotational deformity and shortening are more likely and less angular deformity is acceptable. In general, any rotational deformity should be corrected. Angulation deformities are unacceptable in the index and long finger metacarpals, whereas a small amount of angulation may be compensated for in the ring and little finger metacarpals. Acceptable reduction is less than 10 degrees of angulation in the former and less than 20 degrees in the latter, with less than 3 mm of shortening and normal rotational alignment.[21]

Most metacarpal shaft fractures can be managed initially with ice, limb elevation, analgesia, and immobilization in a gutter splint. The splint should include the wrist and the entire metacarpal shaft, but not the MCP joint if the fracture is proximal to the neck. Repeat radiographic examination and referral to a hand surgeon are recommended. If manipulative reduction is necessary, operative fixation usually is indicated. Multiple displaced metacarpal shaft fractures, oblique or spiral fractures with rotational deformity, irreducible transverse fractures, and displaced open fractures require internal fixation.[31]

Complications.

Complications seen in metacarpal shaft fractures are similar to the complications described for other metacarpal fractures. In addition to malrotation, which can cause a chronic painful grip, limitation of extensor function and interosseous muscle fibrosis may develop.

Metacarpal Base Fractures

Clinical Features. Fractures of the metacarpal base generally are stable and occur infrequently. They may result from either a direct blow over the base of the metacarpal or an axial force or torque applied along the digit. Examination reveals tenderness and swelling at the base of the involved metacarpal, and a significant degree of rotational deformity may be evident. Fractures at the base of the ring or little finger metacarpals may cause injury to the motor branch of the ulnar nerve, resulting in paralysis of the intrinsic hand muscles. In addition, they may be associated with a carpal bone fracture.

www.ketabpezeshki.com 66485457-66963820

Management. Initial management in the ED consists of ice, limb elevation, analgesia, and immobilization in a bulky compressive dressing or volar splint with referral to a hand surgeon for definitive management.

Complications. Metacarpal base fractures may be associated with extensor or flexor tendon damage and significant rotational malalignment. Chronic CMC joint stiffness often is associated with intra-articular fractures and may necessitate arthrodesis or arthroplasty.

Thumb Metacarpal Fractures

Fractures of the thumb metacarpal are relatively uncommon because of its high degree of mobility. Although the shaft occasionally may be involved, most fractures involve the base of the metacarpal. These fractures are classified into two groups: extra-articular and intra-articular. The two common types of intra-articular fractures of the thumb are Bennett's and Rolando's fractures.

Extra-articular Fractures. Extra-articular fractures are seen more commonly than intra-articular fractures and usually result from direct trauma or impaction. The three types of extra-articular fractures are transverse, oblique, and, in children, epiphyseal. Examination reveals localized pain and swelling over the fracture site.

Mobility of the thumb metacarpal allows 20 to 30 degrees of angular deformity without functional impairment. Patients with extra-articular fractures with a greater degree of angulation should undergo closed reduction, postreduction radiographic evaluation, and immobilization of the thumb in abduction with its IP joint extended with a thumb spica cast for 4 weeks. Transverse fractures usually are stable and can be managed with closed reduction and immobilization. If the fracture is oblique, it may require Kirschner wire fixation because of instability and a propensity for rotational deformity.[21]

Intra-articular Fractures

Bennett's Fracture. Bennett's fracture is an intra-articular fracture at the base of the thumb metacarpal combined with a dislocation or subluxation of the CMC joint. The ulnar portion of the metacarpal remains in place, and the larger fragment subluxates dorsally because of the pulling force of the abductor pollicis longus and adductor pollicis muscles (Fig. 50-40). There is complete disruption of the ligaments around the CMC joint. Because stability is conferred mostly by the dorsal ligament (posterior oblique CMC ligament), dislocation ensues. The mechanism of injury usually involves an axial force acting on a partially flexed metacarpal (e.g., striking a rigid object with a closed fist). This is the most common fracture of the thumb base.[32]

Bennett's fracture requires an anatomic reduction. Treatment goals are to achieve stability of the CMC joint by rejoining the volar lip fragment to the first metacarpal and to restore articular congruity. Initial management consists of immobilization in a thumb spica splint, ice, limb elevation, and analgesia. Early referral to a hand surgeon is warranted because although closed reduction can be achieved, the fragments are difficult to hold in position as a result of the pulling forces of the abductor pollicis longus and adductor pollicis muscles. Definitive treatment consists of conservative management, closed reduction with percutaneous pinning, or, if anatomic reduction fails or the fracture fragment represents more than 20% of the articular surface, open reduction and internal fixation.[23]

Rolando's Fracture. *Rolando's fracture* is a comminuted fracture of the base of the thumb metacarpal. Various degrees of comminution occur, but the typical configuration is in a Y- or T-shaped pattern. The severity of comminution often is underrepresented on radiographic studies. The mechanism of injury is the same as in Bennett's fracture, but Rolando's fracture occurs much less commonly and generally carries a much worse prognosis.

Figure 50-40. Bennett's fracture, anteroposterior view. Avulsion fracture of the articular surface of the first metacarpal with subluxation at the carpometacarpal joint *(arrow).* This fracture should be differentiated from Rolando's fracture and the more common extra-articular varieties. (From Rosen P, et al: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1992, p 181.)

ED management of Rolando's fracture consists of immobilization in a thumb spica splint, ice, limb elevation, analgesia, and early referral to a hand surgeon for surgical reduction. Definitive treatment is controversial and depends on the severity of comminution at the base of the thumb and the degree of displacement. If open reduction is indicated, a plate often is placed dorsally to maintain the reconstruction; with severe comminution, Kirschner wire fixation, bone graft placement, and external fixation may be used for continued distraction until healing occurs.[33]

Complications. Complications include joint stiffness, degenerative arthritis, and malunion. Malunion is the most common late complication but usually is well tolerated at the thumb CMC joint.[34] Post-traumatic arthritis is more common after Rolando's fracture and may require arthrodesis or resection hemiarthroplasty. Nonunion is rare.

Pediatric Fractures of the Hand

Pathophysiology and Assessment

The hand is frequently injured in children, with phalanx and metacarpal fractures representing the most commonly fractured bones.[35] In young children, the most common hand fracture involves a crush injury of the fingertip with an open fracture of the distal tuft.[36] The most distinctive feature of the immature skeleton is the presence of epiphyseal growth centers. Although the cartilaginous epiphysis is believed to be a weak link in the immature skeleton, injuries involving this region reportedly account for only 18% of pediatric fractures.[37]

The Salter-Harris classification of epiphyseal fractures is used to direct treatment and predict outcome. The injuries are classified

www.ketabpezeshki.com 66485457-66963820

numerically I through V, with higher numbers corresponding to an increased risk for growth disturbance.[38] The proximal phalanx is the most frequently fractured bone among the phalanges.[39] The most common epiphyseal fracture in the hand is a Salter-Harris type II fracture of the proximal phalanx.[40] It usually results from a twisting or hyperextension mechanism and most often involves the ring and little fingers and the thumb. Although lack of cooperation in this age group may make examination difficult, the clinician should look for swelling, ecchymosis, and deformity. In addition, the examiner should palpate for bony tenderness and for tenderness over the collateral ligaments. Persistent limitation of motion in a young child usually implies a significant injury of the bones or joints of the digit.

Radiologic studies should be obtained and should include the same views that are obtained in an adult. In addition, comparison views may be helpful, particularly in subtle fractures. Epiphyseal fractures may be particularly difficult because pediatric growth plates appear differently at different ages, and their varied radiographic appearance may be mistaken for fractures.

Management

Most pediatric hand fractures can be readily treated with either simple splinting or closed reduction, followed by brief immobilization, usually for no longer than 3 weeks. A plaster or fiberglass gutter splint incorporating the adjacent uninjured finger and including the wrist is the best means of immobilizing a child's finger fracture. The previously mentioned safe position still should be used whenever possible. Some clinicians advocate that in children, even stable injuries that ordinarily would be treated by buddy-splinting in an adult should be protected with full splinting for several weeks to prevent further injury. Open reduction and surgical fixation may be necessary for displaced intra-articular fractures, displaced Salter-Harris type III or IV fractures, and unstable fractures that cannot be maintained by closed methods.[41]

Complications

Pediatric hand fractures heal more quickly compared with similar injuries in adults. In addition, remodeling allows correction of some step-offs or angular deformities in younger children but does not correct rotational deformities. The ability of bone to correct angular deformities by remodeling is diminished with age and cannot be relied on for adequate correction in adolescents and adults. Residual deformity is the most commonly reported complication. Other complications, including joint stiffness, tendon adherence, and nonunion, are rarely seen.

Soft Tissue Injuries

Soft tissue injuries of the hand are extremely common ED presentations.[42] Trauma accounts for most of these injuries to the tendons, ligaments, and cartilage. Although such injuries are not life-threatening, they may result in potentially disabling complications, including deep space infection, osteomyelitis, compartment syndrome, joint laxity, loss of motion, chronic pain, swelling, and deformity.

Dislocations and Ligamentous Injuries

Ligamentous injuries to the hand are common and often missed. Injury may range from mild sprain to complete rupture and may produce various degrees of joint instability. Purely ligamentous injuries may be "tears in continuity" (grade I), partial tears (grade II), or complete tears (grade III). The disruption of joints may be complete, with the articular surfaces completely separated (a dislocation), or incomplete, leaving the articular surfaces in partial communication (a subluxation).

Because the goal of treatment is to restore functional stability, it is essential to perform a systematic evaluation of joint stability. Functionally, stability may be determined through use of a two-phase test of the IP and MCP joints of the hand. Because range of motion is heavily influenced by pain, accurate assessment generally requires digital or wrist block anesthesia in even the most cooperative patients. Active stability is tested by allowing the patient to move the digit through the normal range of motion. Completion of a full range without displacement indicates that adequate joint stability remains. Passive stability is assessed by applying gentle radial and ulnar stress to each collateral ligament and posteroanterior stress to assess volar plate integrity. Stress testing should be done in extended and moderately flexed positions to avoid the stabilizing effect of the volar plate. Comparisons with the same joint of the uninvolved hand may assist in the diagnosis. Supplemental stress radiographs also may be helpful in evaluating difficult cases.[43]

The diagnosis of incomplete or partial ligamentous injuries is made when the joint is stable to active and passive stress but is significantly swollen, with pain elicited on stress and palpation of the involved ligament systems. The examiner should attempt to ascertain whether the most tender area is over the central slip (dorsal), collateral ligaments (radial and ulnar), or volar plate (volar). Grade I and II injuries exhibit stability with pain on stress testing. Grade III injuries show instability on stress testing. Stability of the joint provides strong evidence that optimal functional recovery would result from short-term immobilization rather than surgical intervention. Because of the three-dimensional boxlike configuration that the collateral ligaments and volar plate form around the joint, wide displacement indicates that at least two components of the ligament box complex are disrupted[21,42] (Fig. 50-41). Joints with demonstrable instability should be immobilized in a gutter splint and the patient referred to a hand surgeon to determine whether surgical repair is necessary. Immobilization should be done with the IP joints splinted at 30 degrees of flexion and the MCP joints splinted at 45 to 50 degrees of flexion; when the thumb MCP is involved, it should be splinted in 30 degrees of flexion. Because the long-term effects of joint injuries are almost always joint stiffness and loss of flexion rather than persistent instability, the immobilization period usually is brief (2 to 3 weeks) and should be followed by a gradual procession of active range-of-motion exercises.[21]

Interphalangeal Joint Injuries

Distal Interphalangeal Joint. The DIP joint structure is analogous to that of the PIP joint. Additional stability is provided by the adjacent insertions of the flexor and extensor tendons, and dislocations are uncommon. Most dislocations are dorsal and usually are associated with an open wound (Fig. 50-42). The distal phalanx

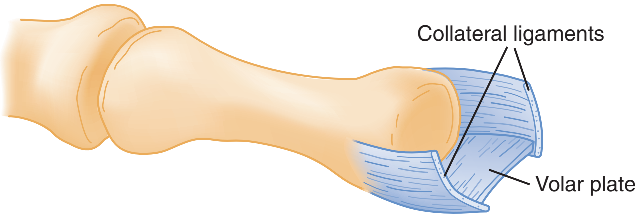

Figure 50-41. The collateral ligaments on either side of the joint and the volar plate form a boxlike support around the joint. (From Simon RR, Koenigsknecht SJ: The hand. In Simon RR [ed]: Emergency Orthopedics: The Extremities, 3rd ed. Norwalk, Conn, Appleton & Lange, 1995.)

www.ketabpezeshki.com 66485457-66963820

Figure 50-42. Dorsal dislocation of the distal interphalangeal joint without associated fracture. (From Harris JH Jr, et al: The Radiology of Emergency Medicine. Baltimore, Williams & Wilkins, 1993, p 446.)

is said to be "bayonet-apposed"—the shafts of distal and middle phalanges lie adjacent to each other, but no bony contact occurs end-to-end at the articular surfaces. Routine radiographs are used more often to rule out associated fractures than to confirm a suspected diagnosis. Treatment consists of closed reduction performed under digital or wrist block anesthesia, followed by active and passive stability testing. Reduction usually is accomplished easily by longitudinal traction and hyperextension to distract the bayonet-apposed distal phalanx followed by direct application of dorsal pressure to the base of the distal phalanx. Irreducible fractures require surgery for open reduction. The irreducibility may be a result of interposition of an avulsed fracture fragment in the joint, entrapment of the profundus tendon, or buttonhole tear through the volar plate.[44]

If the dislocation is open, the joint is contaminated, and treatment should include débridement and copious wound irrigation. The skin should be sutured and the joint splinted in slight flexion with a dorsal splint for 3 weeks. Most authorities recommend prophylactic antibiotics.[44]

Proximal Interphalangeal Joint. Dislocations of the PIP joint are the most common ligament injuries in the hand. Stability is derived from the strong conjoined attachments of the paired collateral ligaments and the volar plate. Three types of displacement of the PIP joint may occur: dorsal, lateral, and volar. The mechanism of injury usually is sports related, with a high-velocity blow to the end of the finger, which causes an axial load and hyperextension. Simple dorsal dislocations result when the volar plate ruptures and the middle phalanx assumes the position of bayonet apposition. Alternatively, a lateral dislocation may result from a radially or ulnarly directed force on the joint that leads to rupture of one collateral ligament and at least partial avulsion of the volar plate from the middle phalanx. In lateral dislocations, the ratio of radial-to-ulnar collateral ligament (UCL) rupture is 6:1, and the digit usually is ulnarly deviated. Volar dislocation of the PIP joint is rare. The most common mechanism of injury is a rotary longitudinal compression force on a semiflexed middle phalanx that results in unilateral disruption of a collateral ligament and partial avulsion of the volar plate. Physical examination reveals swelling and tenderness over the PIP joint and inability to extend the joint. Routine radiographs of the injured digit reveal the type of dislocation and any associated avulsion fractures.

Management. Small bone fragments at attachment sites seen on radiographs are associated with avulsions of minor ligamentous attachment points and do not indicate the need for open repair. Avulsion fractures involving 33% or more of the articular surface usually are unstable and require surgery.[45]

Most closed dorsal and lateral PIP dislocations are treated nonoperatively.[44] Reduction is facilitated by digital nerve block and usually can be accomplished by longitudinal traction and mild hyperextension followed by firm dorsal pressure on the proximal aspect of the middle phalanx. When reduction has been achieved, active motion is tested. Reduction is stable if no displacement occurs during active range of motion and passive stressing of the joint. More than 20 degrees of deformity and instability with lateral testing indicate a complete ligamentous injury.[46] If stability is maintained during active range of motion, treatment consists of 3 weeks of immobilization in 20 to 30 degrees of flexion, followed by active exercises. Although stiffness, pain, and swelling are likely to persist for months, the long-term prognosis is good, and subluxation usually does not recur unless the finger is hyperextended again.[44] If the dislocation is irreducible or there is evidence of complete ligamentous disruption with dislocation on active range of motion, operative repair is required.

The management of volar dislocations of the PIP joint is controversial. The dislocation has been described as irreducible and requiring open reduction; however, some authorities state that most volar dislocations can be reduced by a closed technique of applying gentle traction with MCP and PIP joints flexed.[44] A stable reduction with repair of the soft tissue structures and transarticular pinning in the fully extended position also has been recommended.[44]

Injury to the Metacarpophalangeal Joints of the Fingers

Pathophysiology. MCP dislocations are considerably less common than dislocations of the PIP joint. The MCP joints of the fingers are resistant to ligamentous injury and dislocation because of their inherent ligamentous structure, their surrounding supporting structures, and their protected position at the base of the fingers. Like the DIP and PIP joints, each MCP joint has two collateral ligaments and a volar fibrocartilaginous plate; however, the MCP joints are condyloid joints and permit, in addition to flexion and extension, 30 degrees of lateral motion while the joint is extended. Because of the shape of this articulation, the joint is more stable in flexion when the collateral ligaments are stretched than when they are in extension. They are most vulnerable to injury from forces directed ulnarly and dorsally.

Isolated injury to the collateral ligaments and volar plate of the MCP joint is rare. These injuries usually occur with hyperextension stress applied to the MCP joint with the finger extended. The patient has ecchymosis and swelling of the joint. Examination reveals tenderness along the joint and varying degrees of instability. The radiographic appearance usually is normal on routine views, but some clinicians recommend a Brewerton view to show any evidence of avulsed bone fragments.[47] Treatment for most of these injuries consists of application of a gentle compression dressing with light plaster reinforcement and early orthopedic referral.

Dislocations of the MCP joints of the fingers are relatively rare injuries and usually are dorsal. The most common digit involved is the index finger, followed by the little finger. These dislocations result from hyperextension forces that rupture the proximal volar plate and are divided into simple and complex types. In the simple dislocation (subluxation), the joint appears to be hyperextended to 60 to 90 degrees, and the articular surfaces are in contact without interposed soft tissue. With complex (complete) dislocations, the MCP joint is in moderate hyperextension and angulated, the metacarpal head is prominent in the palm, and the distended palmar skin is dimpled. Complex dislocations have a less striking

www.ketabpezeshki.com 66485457-66963820

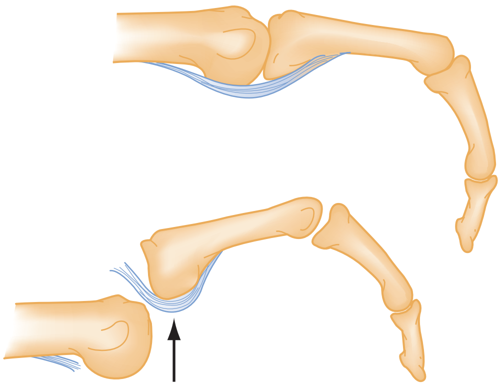

Figure 50-43. The most important element preventing reduction in a complex metacarpophalangeal dislocation is interposition of the volar plate within the joint space *(arrow).* It typically requires surgical extrication. (From Green DP, Rowland SA: Fractures and dislocations in the hand. In Rockwood CA Jr, Green DP [eds]: Fractures in Adults. Philadelphia, JB Lippincott, 1991, p 521.)

Figure 50-44. A pathognomonic radiographic sign of complex metacarpophalangeal dislocation is the presence of a sesamoid bone in the widened joint space, indicative of interposition of the entrapped volar plate. (From DeLee JC, Drez D Jr, Miller MD: Orthopedic Sports Medicine: Principles and Practice, 2nd ed, vol 2. Philadelphia, Saunders, 2003, p 1387.)

presentation but represent a more severe injury; the volar plate is interposed in the MCP joint space, and closed reduction is not possible (Fig. 50-43). Radiographic examination shows an obvious dislocation on the lateral view. Posteroanterior views reveal widening of the joint space in complex dislocations. In addition, sesamoid bones may be seen in the joint; this finding is pathognomonic for this injury (Fig. 50-44).

Management. After appropriate anesthesia is obtained, simple dorsal dislocations should be reduced in a way that prevents entrapment of the volar plate in the joint. Reduction is accomplished by flexing the wrist to relax the flexor tendons and

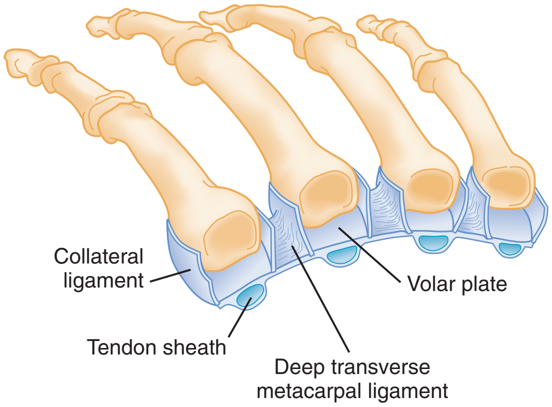

Figure 50-45. The volar plates of four palmar metacarpals are held together firmly by the deep transverse metacarpal ligament, which is continuous with the volar plate. Eaton calls this the "intervolar plate ligament." (From Green DP, Rowland SA: Fractures and dislocations in the hand. In Rockwood CA Jr, Green DP [eds]: Fractures in Adults. Philadelphia, JB Lippincott, 1991, p 518.)

applying firm pressure over the dorsum of the proximal phalanx in a distal and volar direction. Excessive hyperextension or longitudinal traction should be avoided. The MCP joints should be splinted in flexion, and referral to a hand surgeon is necessary. Complex dorsal dislocations do not reduce with closed methods and require operative reduction. Volar dislocations are rare and generally require operative reduction.

Injury to the Carpometacarpal Joints of the Fingers

Pathophysiology. The CMC joints of the digit form the base of the transverse metacarpal arch of the hand. The metacarpal bases articulate with one another and with the distal carpal row in a complex interlocking structural arrangement. The joints are supported by strong dorsal, volar, and interosseous ligaments and are reinforced by the broad insertions of the wrist flexors and extensors (Fig. 50-45). Dislocations of the CMC joints are uncommon and often are missed.[48] Overall, the most commonly injured CMC joint is the little finger, and most of these injuries are dorsal fracture-dislocations.[49] The injury occurs as a result of motor vehicle collisions, falls, crushes, and closed-fist trauma.

Clinical Features and Diagnostic Strategies. Clinically, the patient has swelling on the dorsum of the hand and tenderness over the involved CMC joints. Routine radiographs should be viewed carefully because fracture lines may be subtle, and the metacarpals may be obscured by superimposition. Other radiographic views that may be helpful include multiple oblique, forearm in 30-degree pronation, and Brewerton views.[49]

Management. Initial treatment consists of ice for comfort, limb elevation, and analgesia. Closed reduction of the dorsal fracture-dislocation may be attempted after adequate regional anesthesia has been obtained. Traction and flexion with simultaneous longitudinal pressure on the metacarpal base, followed by extension of the metacarpal head when length has been restored, generally result in reduction. Even in cases in which reduction is achieved by closed means, early referral to a hand surgeon is needed because Kirschner wire fixation is advisable to ensure adequate stability. The late sequelae of fracture-dislocations include pain and weakness from traumatic arthritis secondary to imprecise alignment or chronic dislocation of the CMC joints.

Injury to the Interphalangeal Joint of the Thumb

The IP joint of the thumb is similar to a finger DIP joint except that the phalanges of the thumb typically are larger and stronger

www.ketabpezeshki.com 66485457-66963820

than the phalanges of the fingers. Even with the thumb's vulnerable position, IP dislocation is uncommon. Most dislocations are dorsal, and they often are associated with open injuries. Reduction usually is simple after a median nerve block. The joint usually remains stable because the volar plate remains attached to the distal phalanx, and immobilization in mild flexion for 3 weeks usually suffices for successful management.

Injury to the Metacarpophalangeal Joint of the Thumb

The MCP joint of the thumb is a condyloid joint that allows mainly flexion and extension; however, it also permits some degree of abduction, adduction, and rotation. Its volar plate and collateral ligaments are stronger than in other MCP joints, but its vulnerable position leads to frequent traumatic injury. Overall, injury to the MCP joint of the thumb accounts for five times the number of injuries of all other MCP joints combined.

Most dislocations of thumb MCP joints are dorsal and result from a hyperextension force that ruptures the volar plate, joint capsule, and at least part of the collateral ligament. As with other dorsal MCP dislocations, displacement ranges in extent from subluxation of the phalanx to a complex dislocation with the proximal phalanx resting over the metacarpal head. The complex dislocation is not easily reduced because of volar plate entrapment in the joint. Clinically, the complex dislocation may show a dimple over the thenar eminence. Radiographic studies confirm the dorsal dislocation and reveal the sesamoids in close proximity to the proximal phalanx.

Management. Closed reduction may be attempted after radial and median nerve wrist block anesthesia has been achieved. Pressure is directed distally on the base of the proximal phalanx, with the metacarpal flexed and adducted. If reduction is difficult, the IP joint and wrist can be flexed to relax the entrapped flexor pollicis longus tendon. When restoration of anatomic position has been accomplished, the collateral ligaments should be tested, and reduction should be confirmed by radiographic assessment. Stability to active range of motion and stress testing suggests that immobilization in a thumb spica splint with the MCP joint in 20 degrees of flexion for 4 weeks constitutes adequate treatment. Nonreducible (complex) dislocations or dislocations with significant lateral instability require open reduction and operative repair. Hyperextension, instability, and chronic pain on pinching may occur after these injuries.

Ulnar Collateral Ligament Injuries (Gamekeeper's Thumb, Skier's Thumb)

Pathophysiology. Injury to the UCL was first described as an occupational hazard of Scottish gamekeepers, who damaged their thumbs by a repeated maneuver involving twisting the necks of hares.[50] Skiing is now the most common cause of acute and chronic injury to the UCL.[51] *Skier's thumb* is the most common upper extremity injury in skiing and results from interference with release of the pole at the moment of impact during a fall. UCL rupture occurs 10 times more often than radial collateral ligament injury.[52] The mechanism of injury is forced radial deviation (abduction), and the subsequent tear usually occurs at the insertion into the proximal phalanx. Stener[53] showed that in nearly two thirds of cases of complete UCL rupture, the adductor pollicis becomes interposed between the superficial proximal portion and the deep distal portion of the ligament (see Fig. 50-45). Besides the collateral ligament injury, associated injuries of the dorsal capsule and volar plate are common.

Clinical Features. Physical examination reveals swelling and localized tenderness over the ulnar border of the joint and weakness of pinch. Complete and partial ruptures usually can be differentiated by clinical examination. Valgus stress testing of the UCLs is required and should be performed with the joint in full extension and in 30 degrees of flexion to avoid the stabilizing effect of the volar plate. If the examination elicits pain and guarding, the test should be done after median and radial nerve block at the wrist or with use of local infiltration anesthesia. More than 35 degrees of joint laxity or 15 degrees of laxity beyond that present in the uninjured thumb is consistent with complete UCL rupture.[54] Routine radiographs should be obtained before the joint is stressed and may reveal a bony avulsion from the insertion of the UCL into the proximal phalanx or an associated condylar fracture. Radiographic findings of proximal phalanx volar subluxation and radial deviation may indicate complete UCL rupture.[55] Because of the difficulty in diagnosing complete rupture, it is commonly misdiagnosed as a simple sprain in the ED, potentially resulting in chronic disability.[56]

Management. Acute partial ruptures of the UCL can be treated effectively with a 4-week period of immobilization in a thumb spica cast; full recovery is the rule. Complete ligament tears require surgical repair because a high percentage are associated with soft tissue interposition from the adductor aponeurosis (Stener's lesion), with limited predicted healing potential. Anatomic repair within 3 weeks of injury achieves good or excellent results in 90% of affected patients.[57] Long-term complications include chronic pain and instability with the loss of pinch strength, which may necessitate arthrodesis.

Radial Collateral Ligament Injuries

Radial collateral ligament injuries of the MCP joint of the thumb are less common but equally debilitating.[52] The usual mechanism is forced adduction with or without hyperextension. Diagnosis and treatment generally are similar to those for UCL injuries. There have been isolated case reports of a Stener-like lesion on the radial side, with some authors advocating for the role of surgical repair.[58]

Injuries to the Carpometacarpal Joint of the Thumb

Injuries of the volar ligament of the thumb CMC joint, similar to those of other joints of the hand, may be complete or partial. Complete rupture permits the entire thumb metacarpal to dislocate dorsally. Controversy exists regarding the ligament most responsible for stability of the thumb CMC joint, although most recent evidence implicates the dorsoradial ligament in dislocations at this joint.[59] These dislocations are reduced easily but are unstable after reduction. Initial management consists of ice, analgesia, limb elevation, and application of a thumb spica splint. The patient should be promptly referred to a hand surgeon for possible operative repair of the ligament. If the capsule is allowed to heal with imperfect metacarpal reduction, joint instability may result, with progressive degenerative changes leading to chronic pain.

Tendon Injuries

Tendon injuries may involve one or more of the extensor or flexor tendons in the hand and encompass a spectrum of abnormalities, ranging from simple stretching of the fibers to complete tendon rupture with or without an associated avulsion fracture. The most common mechanisms of injury of tendons are lacerations, avulsions, and crush injuries. In a normal resting position, the fingers are flexed, with the little finger having the greatest degree of flexion and the index finger having the least. In the resting hand, a finger with a greater or lesser degree of flexion than that of the opposite hand often indicates a tendon injury. This observation may be especially useful in an uncooperative or pediatric patient. If the patient can move a joint, but active flexion or extension is limited

www.ketabpezeshki.com 66485457-66963820

or painful, a partial tendon laceration may be present. To assess the tendons adequately, motion should be tested against resistance. This testing may cause a partially ruptured tendon to rupture but identifies a lesion that needs surgical repair. The tendon should be placed in maximal stretch before testing to provide for the greatest strength during contraction. As a general rule, extensor injury causes greater impairment of motion than a similar flexor injury. Vessels and nerves travel closely with flexor tendons, particularly in the fingers. Damage to one of these structures is likely to be associated with damage to the other two.

The position the hand was in when the injury occurred is important. When trauma occurs while the hand is held in flexion, the flexor tendons may be transected, and the distal tendon stump would retract distal to the overlying skin wound. If the hand is in the extended position, however, the tendon stumps would lie at the wound edges. When the tendons are injured by a direct blow to the hand or the fingers, the closed injury may hide significant tissue damage. Partial tendon lacerations may be associated with small surface wounds. To help exclude injury, wounds and visible tendons should be inspected while the joints are taken through a full range of motion.

Extensor Tendon Injuries

The most common site of tendon injury is the extensors over the dorsum of the hand. The extensors are predisposed to laceration because of their superficial location on the dorsum of the hand and the minimal amount of subcutaneous tissue between the tendon and overlying skin. This anatomic arrangement also predisposes the extensor mechanism to more complex tendon injuries, including abrasion, crush, and avulsion. Because the extensor tendons are not constrained in tight fibro-osseous canals except in the wrist, they also are easily located and repaired.

Injuries to the extensor tendons have been grouped into anatomic zones for easy understanding and classification. Different systems for assigning zones have been described, but the most widely accepted is that of Verdan[60] (Fig. 50-46). This system defines eight zones, from zone I at the DIP joint level to zone VIII at the distal forearm level. The use of zones is convenient for assessing injury patterns, repair techniques, and rehabilitation.

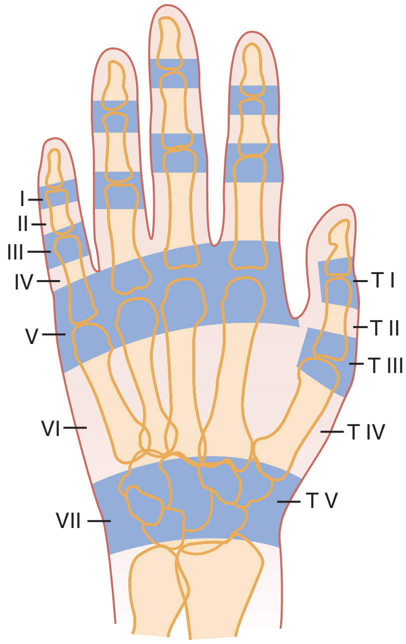

Figure 50-46. Zone classification for extensor tendon injuries. (From Kleinert HE, et al: Flexor tendon injuries. Surg Clin North Am 61:267, 1981.)

Zone I Injuries

Pathophysiology. Zone I is the area over the distal phalanx and DIP joint. In this region, the conjoint extensor tendon is well defined and dorsally positioned. Injuries that occur here disrupt the terminal extensor tendon; they may be open or closed and may occur with or without a fracture. Complete laceration of the conjoint tendon results in a flexed posture of approximately 40 degrees at the DIP joint. Partial transection results in a lesser extension lag and a decrease in the strength of extension against resistance from a flexed position. The extension lag may increase if the partial injury is not treated appropriately. For this reason, exploration of dorsal lacerations near the DIP joint is important.

Mallet finger is the most common injury in zone I and refers to a closed disruption of the distal extensor apparatus.[21] As a result of loss of extensor tendon continuity to the distal phalanx, there is a flexion deformity of the DIP joint. The injury can be seen in any finger but is most common in the long, ring, and little fingers. Overall, mallet finger represents the most common tendon injury in the hand seen in athletes.[61] The mechanism of injury often is sudden forceful flexion of an extended finger when an object, such as a ball, strikes the tip of the finger. This mechanism is commonly encountered in athletes and often is described as "jamming" the finger. Other mechanisms include hyperextension with axial compression and direct crush injury at the DIP joint. Four types of injury patterns are recognized, with type 1 injuries being the most common (Fig. 50-47 and Box 50-2). Fracture fragments of

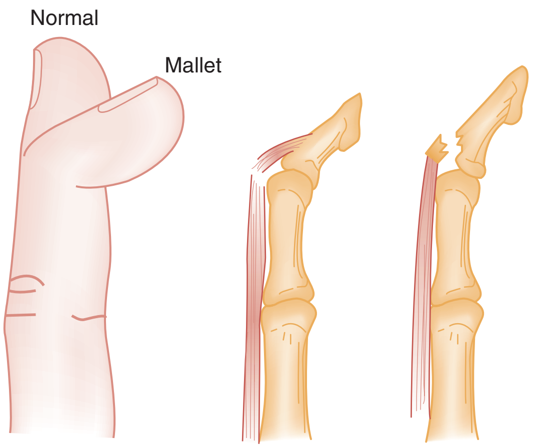

Figure 50-47. Mallet finger occurs with loss of extensor function to the distal phalanx. This may be caused by a tear of the tendon itself or an avulsion fracture of the dorsal base of the distal phalanx.

Box 50-2 Classification of Mallet Fingers (Doyle)

Type I—Closed tendon rupture, with or without small dorsal avulsion fracture
Type II—Open tendon laceration
Type III—Open tendon injury with skin and subcutaneous tissue loss
Type IV—Mallet fracture
- A. Transepiphyseal plate fracture in children
- B. Hyperflexion injury with fracture of articular surface of 20 to 50%
- C. Hyperextension injury with fracture of the articular surface >50% and with early or late volar subluxation of distal phalanx

From Strauch RJ: Extensor tendon injury. In Wolfe SW, Hotchkiss RN, Pederson WC, Kozin SH [eds]: Green's Operative Hand Surgery, 6th ed. Philadelphia, Churchill Livingstone, 2011, p 169.

www.ketabpezeshki.com 66485457-66963820

Figure 50-48. Mallet finger fracture, lateral view. This is an intra-articular avulsion of the dorsal surface of the distal phalanx *(arrow)*. (From Rosen P, et al: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1992, p 181.)

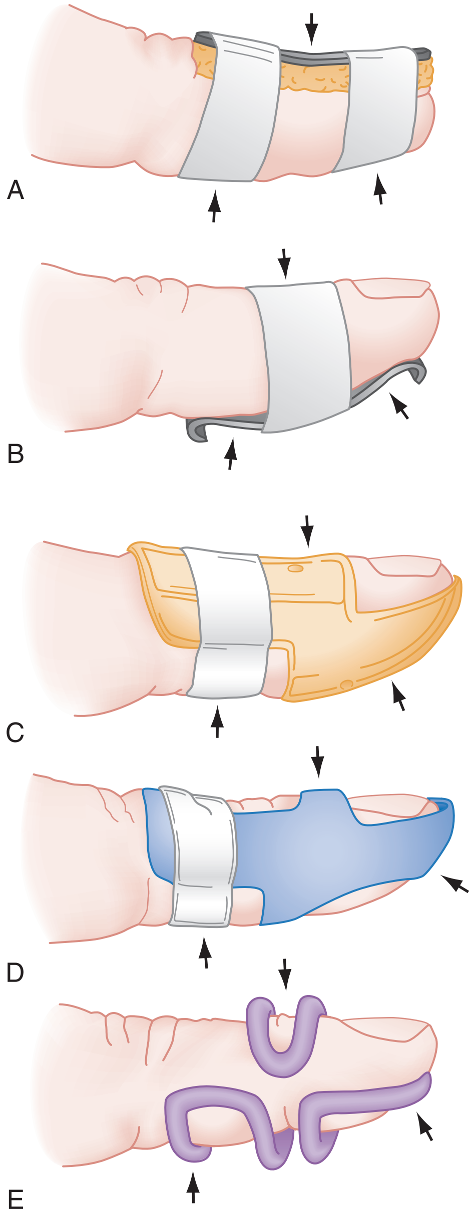

Figure 50-49. Only the distal interphalangeal joint is immobilized in treating mallet fingers. This may be done with a dorsal padded aluminum splint **(A)**, a volar unpadded aluminum splint **(B)**, a Stack splint **(C)**, a modified Stack splint **(D)**, or an Abouna splint **(E)**. Each of these splints uses a three-point *(arrows)* fixation principle. (From Green DP, Rowland SA: Fractures and dislocations in the hand. In Rockwood CA Jr, Green DP [eds]: Fractures in Adults. Philadelphia, JB Lippincott, 1991, p 450.)

variable size are seen in one fourth to one third of cases (Fig. 50-48). Small avulsion fractures usually are the result of hyperflexion injuries, whereas large fracture fragments usually result from a hyperextension mechanism.[62]

Clinical Features. In the acute injury, clinical findings include swelling, pain, and tenderness over the DIP joint. The distal phalanx is flexed because of the unopposed action of the FDP. There is usually complete passive but incomplete active extension at the DIP joint. Although the diagnosis is easily made, the patient often seeks treatment late because the functional disability is not great.

Management. Although various treatment protocols have been proposed, splinting of the IP joint for 6 to 8 weeks has yielded good results while minimizing morbidity in a majority of patients. The primary goal of treatment is the maintenance of continuous DIP joint extension until tendon healing occurs. Treatment of closed (type I) injuries is nonoperative. Immobilization can be accomplished with either a volar or a dorsal splint made from a variety of materials, including aluminum and plastic (Fig. 50-49). The DIP joint is immobilized in slight hyperextension for 6 to 8 weeks, but the PIP and MCP joints are allowed to move freely.[21] An excessive degree of hyperextension should be avoided because this can lead to skin necrosis on the dorsal surface of the DIP joint.[63]

Open zone I injuries that divide the extensor tendon (mallet finger types II and III) are treated by suturing the cut ends (Fig. 50-50). Partial and compete lacerations are repaired with either a roll suture or figure-of-eight stitch with 5-0 nonabsorbable sutures. This repair should be followed by continuous splinting of the DIP joint in full extension for a minimum of 6 weeks.[60]

Definitive treatment of a type IV injury is controversial. Some authorities recommend operative repair; others recommend conservative management with uninterrupted splinting of the digit.[60]

Prognosis. More than 80% of patients who receive conservative treatment for mallet finger report successful outcomes; however, most patients do not regain full mobility at the DIP joint.[64] Possible delayed complications include dorsal deformity, cold intolerance, pain, and the so-called *swan neck deformity* (Fig. 50-51). This abnormality develops when the lateral bands displace proximally and dorsally, resulting in increased extension forces on the PIP joint. Secondarily, the extensor lag at the DIP joint increases because the force of the FDP tendon is unopposed. The swan neck deformity is not seen acutely unless the injured finger has a normally hyperextended PIP joint. Classically, this deformity occurs as a complication of a chronic untreated mallet finger.[60]

www.ketabpezeshki.com 66485457-66963820

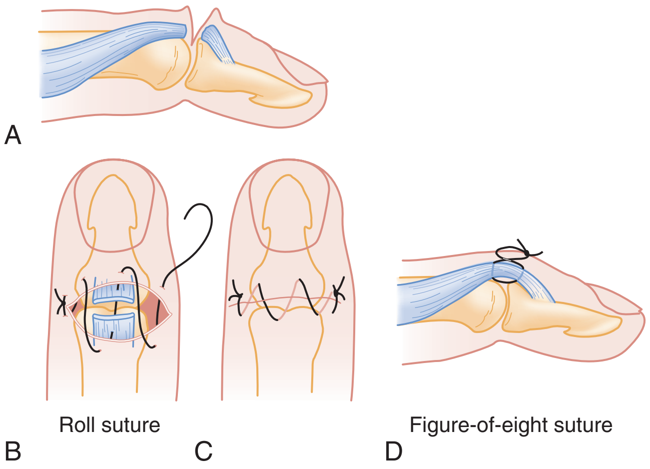

Figure 50-50. Lacerations of the extensor mechanism over the distal joint with mallet finger deformity **(A)** can be repaired by a roll-type suture, which simultaneously approximates skin and tendon (**B** and **C**). A small dressing is applied with a splint to maintain the joint in full extension. Sutures are removed at 10 to 12 days. A figure-of-eight vertical suture **(D)** also may be used, which simultaneously closes the defect in tendon and skin. Splinting is mandatory for 6 weeks. (From Doyle JR: Extensor tendons-acute injuries. In Green DP [ed]: Operative Hand Surgery. New York, Churchill Livingstone, 1993, p 1939.)

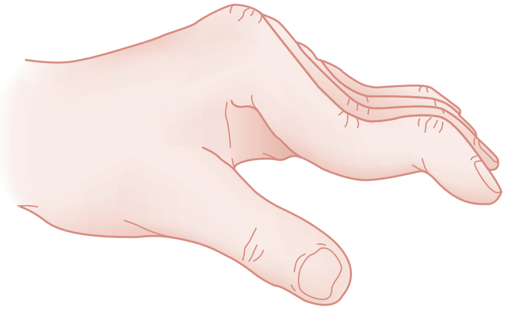

Figure 50-51. Swan neck deformity of the fingers.

Zone II Injuries. Zone II is the area over the middle phalanx. As the lateral bands blend dorsally to form the conjoint tendon, they are thin and oriented around the dorsal half of the middle phalanx. Injuries here usually are the result of a simple laceration, which seldom transects all of the dorsal apparatus. Examination reveals a typical mallet deformity. The treatment is identical to that for open zone I injuries.

Zone III Injuries

Pathophysiology. Zone III is the area over the PIP joint. The central tendon is the most commonly injured structure in this zone; such injuries are the second most common closed tendon injury in athletes.[61] The mechanisms for closed rupture include forced flexion of an actively extended finger, a direct blow to the dorsum of the PIP joint, and hyperextension with volar dislocation of the PIP joint. It often results from a “jamming” injury. Lacerations that occur just distal to the PIP joint also may divide the central tendon and readily extend into the joint. Wounds are carefully explored to define the status of the PIP joint capsule.

Disruption of the central tendon causes an imbalance in the extensor mechanism. The FDS is now unopposed and flexes the PIP joint. The lateral bands displace volarly to the axis of the PIP joint and become flexors of the joint. In addition, the extensor hood retracts proximally, causing extension of the MCP and DIP joints. The resulting tendon imbalance leads to the so-called *boutonnière* (buttonhole) deformity, with flexion of the PIP joint

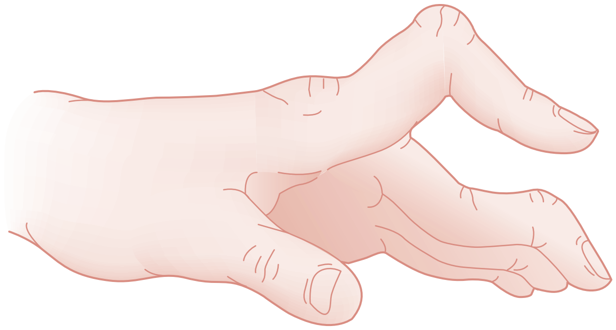

Figure 50-52. Buttonhole (boutonnière) deformity of the index finger, with swan neck deformity of the other fingers.

and hyperextension of the DIP and MP joints (Fig. 50-52). Although open injuries of the central tendon may cause an acute boutonnière deformity, this usually is delayed several weeks after a closed athletic injury.

Clinical Features. Early diagnosis of a closed central tendon rupture or avulsion is difficult before the boutonnière deformity has developed. The patient typically has a history of trauma to the involved digit and a painful, swollen PIP joint. The finger is held in slight flexion at the PIP joint and slight extension at the DIP joint. Rupture of the central tendon may be differentiated from the more common injury to the collateral ligament by the location of the maximal area of tenderness on the dorsum rather than on the sides of the joint, and by the patient’s inability to extend the PIP joint actively. PIP joint extension can be tested by having the patient attempt to extend the fingers against slight resistance with the hand flat on the table and the PIP joint flexed 90 degrees over an edge of a table (Elson’s test). A positive Elson’s test result, indicative of rupture of the central tendon slip, occurs when the DIP joint is held in fixed extension or hyperextension, with the absence of PIP joint extension.[65] During the acute phase of an injury, a digital block may be necessary to facilitate performance of the Elson test.[60] The radiographic appearance of a central tendon rupture typically is normal but may be diagnostic if an avulsion fracture of the volar base of the middle phalanx is visualized on the lateral view.

Management. Patients with suspected closed central tendon injuries should be managed with splinting of the PIP joint in full extension for 5 to 6 weeks. Only the PIP joint should be immobilized, and passive and active DIP joint flexion is encouraged from the outset. Operative repair may be required for an acute closed boutonnière injury associated with a displaced avulsion fracture and injury with volar PIP joint dislocation. Early referral to a hand surgeon is advised.

When an acute boutonnière deformity is caused by an open injury, exploration of the central slip is mandatory and a hand surgeon should be consulted immediately. Primary repair of the tendon and Kirschner wire fixation of the PIP joint often are performed. If the joint capsule has been violated, the joint should be thoroughly débrided and irrigated, and the use of prophylactic antibiotics is recommended.

Zone IV Injuries. Zone IV includes the area over the proximal phalanx. The clinical findings are similar to those with zone III injury but are less severe because the PIP joint and lateral bands are intact. The resulting injury usually is partial, and the tendon ends usually do not retract appreciably. These injuries are treated with primary or delayed primary repair and appropriate splinting for 3 to 6 weeks. Simple injuries in this zone can be well approximated with 5-0 nonabsorbable sutures with buried knots. Immobilization should be done with maintenance of the wrist in extension and the MCP joints in approximately 15 degrees of

www.ketabpezeshki.com 66485457-66963820

flexion. Tendon adhesions are common in this zone because of associated damage to the periosteum.

Zone V Injuries. Zone V injuries involve the areas over the MCP joint and should be presumed to be the result of a human bite until proven otherwise. These injuries occur most commonly over the MCP joints of the long and ring fingers. Radiographs are mandatory and may include Brewerton views to assess the metacarpal head closely for injury. The clinical findings with injuries to the extensor tendon at this level are flexion of the MCP joint and inability to extend the joint fully.

In an open joint injury caused by a human bite, the potential for mixed aerobic and anaerobic infections is high. Operative exploration, débridement, and irrigation are necessary. A combination of a β-lactam and a β-lactamase inhibitor drug is recommended empirically for infections related to human bites.[28] In penicillin-allergic patients, clindamycin in combination with a fluoroquinolone may be given.[28] The wound is left open and may be closed at 4 to 5 days if free from infection. The resultant tendon injury usually is only a partial laceration, which may be managed with primary or delayed primary repair.

For simple lacerations at this level caused by a sharp, clean object, primary repair is indicated. The involved tendon ends do not retract and can be approximated with 4-0 nonabsorbable sutures. Sagittal bands also should be repaired if injured to prevent loss of extension or subluxation. The wrist and MCP joints should be immobilized. Early referral to a hand surgeon is advised.

Zone VI Injuries. Zone VI includes the area of the dorsum of the hand. Although these injuries may be similar in clinical appearance to zone V injuries, the joint is not involved, and these injuries generally are not as severe. Because the extensor tendons are superficial at this level, a relatively trivial-appearing skin laceration may be associated with one or more tendon lacerations. If the injury is proximal to the juncturae tendinum, the patient may be able to extend the involved MCP joint because weak extensor forces are transmitted to the junctura from adjacent extensor tendons.

The tendons in this area are round or oval and easily exposed. Primary repair with a modified Kessler stitch with a 4-0 nonabsorbable material or a figure-of-eight stitch with a buried knot on the deep, palmar surface of the tendon suffices. This repair is followed by immobilization of the wrist at 30 degrees of extension and the MCP joint in neutral position. Referral to a hand surgeon for delayed primary repair also is appropriate.

Zone VII and VIII Injuries. Zone VII and VIII injuries involve the wrist and forearm. Management follows basic principles for tendon injuries.

Flexor Tendon Injuries

Pathophysiology. Flexor tendon injuries are not as common as injuries to the extensor complex and often have a subtle clinical presentation. The most common mechanism of injury is laceration, but closed traumatic disruption also may occur. FDP avulsion is the third most common tendon rupture in the hand in athletes.[61] This injury usually is sports-related and involves a hyperextension force applied to an actively flexing digit; the classic example is that of an injured digit in a football player who grabs the clothing of an opponent who is breaking free from a tackle. Most of these injuries involve the ring finger, possibly because the ring finger becomes the most prominent finger with the fingers held in a partially flexed position.[66] Because of the closed nature of these injuries, the patient may not seek immediate care, or the condition initially may be misdiagnosed.

Clinical Features. Careful assessment is necessary to diagnose flexor tendon disruption and associated neurovascular injury. With the normal hand at rest, there is a cascade of flexion of the digits, beginning with less flexion at the index finger and progressing to more flexion toward the little finger. An injury to a flexor tendon may be evident if the involved finger does not assume a naturally flexed position. Complete disruption of the profundus tendon results in an extended position of the DIP joint as a result of unopposed extensor forces. If the FDS is completely severed, or a partial tendon injury has occurred, the digit rests in less flexion than normal. An abnormal posture of the injured digit may suggest a flexor tendon injury; this usually is confirmed by a functional examination. The FDP and the FDS should be tested separately as previously described. This examination requires careful observation: The patient may flex the distal tip with an intact profundus, but an injury to the FDS precludes flexion at the PIP joint. Disruption of the FDP tendon leads to loss of flexion at the DIP joint, instability in pinch, and loss of grip strength. FDP avulsions can be classified into three types. Type I injuries involve retraction of the avulsed FDP tendon into the palm, damaging the blood supply to the tendon and causing hematoma formation in the process. Because of the damaged vasculature, these injuries should be repaired urgently to prevent ischemic tendon damage.[67] Types II and III injuries cause lesser degrees of retraction of the FDP tendon. Accordingly, these injuries result in less compromise of the tendon's blood supply and have more favorable outcomes.[67] FDP injuries may be present if the patient complains of subjective weakness or if an abnormal position of the hand is observed at rest. Clinically, injuries are associated with pain and weakness with flexion against resistance. Despite these findings, it may not be possible to arrive at a complete and accurate diagnosis until the wound is surgically explored. The palmaris longus, which is not present in approximately 15% of people, is not a functionally significant wrist flexor. Palmaris longus lacerations have tremendous diagnostic significance, however, because most of these injuries (80 to 90%) are associated with concomitant partial or complete median nerve lacerations. For this reason, all patients with palmaris longus lacerations should be assumed to have median nerve laceration until such injury has been ruled out clinically or by direct examination.[68]

Management. Flexor tendon repairs require the expertise of a hand surgeon and generally are not repaired by emergency physicians. Immediate or delayed primary repair is now advocated for most acute flexor tendon injuries, including avulsions of the FDP and injuries involving the so-called "no man's land," which extends from the distal palmar crease to the midportion of the middle phalanx. The term "no man's land" refers to the high frequency of tendon adhesion after injury in this area. The advantages of primary repair with surgical reapproximation over secondary grafting for treatment of acute injuries have been well described in the literature.[69] Emergent repair of lacerated flexor tendons is indicated in the setting of diminished circulation to the digit requiring vascular repair. Otherwise, early definitive repair can be undertaken within days of the injury.[69] Secondary repair of flexor tendons may be performed 4 weeks after injury, but repair is considered late after that. In general, the results of primary, delayed primary, and early secondary repair are approximately equal. Treatment of partial flexor tendon lacerations is controversial, but referral to a hand surgeon for further exploration and possible repair is prudent.

If a hand surgeon is not immediately available, open wounds should be copiously irrigated and closed with 5-0 nylon and the hand splinted with the wrist in 30 degrees of flexion—the MCP joints flexed approximately 70 degrees and the IP joint flexed 10 to 15 degrees. This flexion ensures that no further damage occurs to the tendon and that the tendon will not contract further on movement. The patient also should receive tetanus immunization as indicated, and most authorities recommend empirical use of broad-spectrum antibiotics. Most closed tendon injuries require referral to a hand surgeon because of the risk of long-term disability.

www.ketabpezeshki.com 66485457-66963820

Complications. With optimal management, most patients with flexor tendon injuries have good to excellent outcomes.[70] With injuries involving the no man's land, results may be poor, and tendon grafting occasionally is required. Overall, adhesions remain the most significant problem after operative repair. Other complications include triggering, bowstringing, and intratendinous epidermoid cyst formation.[71]

Mutilating Injuries

Mutilating injuries to the hand are encountered frequently in the ED. These are severe multistructural injuries that destroy the anatomy and functional integrity of the hand. Initial evaluation should focus on preservation of vital structures, analgesics, early consultation, wound care with débridement of devitalized tissue, and antibiotics. Evolving over recent years is a more aggressive push with respect to procedure timing, whether a single-stage or multistage strategy is used.[72] Successful long-term clinical and socioeconomic outcomes have brought focused attention on procedure timing. The concept of early primary reconstruction with fast rehabilitation should be pursued based on case profile.[72] One such type is snowblower-, wood chipper–, or lawnmower-associated hand injuries, which can result in substantial deformity and disability. Snowblower injuries typically occur in clusters and are responsible for approximately 1000 amputations and 5000 ED visits annually.[73] The dominant hand is involved approximately 68% of the time, with middle and index fingers most commonly injured. Phalangeal fractures are the most common type of injury.[74] Snowblower injuries often are managed as open fractures with intravenous antibiotics, irrigation, and débridement and repair of bone, soft tissue, and nail bed structures.[74] Irreparable devascularization currently is considered the only absolute indication for immediate or early digital amputation after injury.[75] The concept and techniques for reimplantation and revascularization in mutilating injuries in children are similar to those in adults.[76]

Fingertip Injuries

Fingertip injuries may involve any structures distal to the DIP joint, including the skin, volar pulp tissue, distal phalanx, nail, nail bed, and related structures. These are among the most common injuries of the upper extremity and, although usually minor, may have significant long-term consequences. The goals of management are to maintain finger length and to achieve good tissue coverage, near-normal sensibility, and early functional recovery.

Fingertip Amputations

Classification. Fingertip amputations are the most common type of amputation of the upper extremity. In zone I injuries (Fig. 50-53), the proximal two thirds of the nail bed is preserved. In zone II injuries, bone is exposed, and in zone III injuries, the entire nail bed is lost. Radiographic studies are indicated if bony avulsion injury or fracture cannot be excluded. Most of these fingertip injuries can be managed on an outpatient basis.

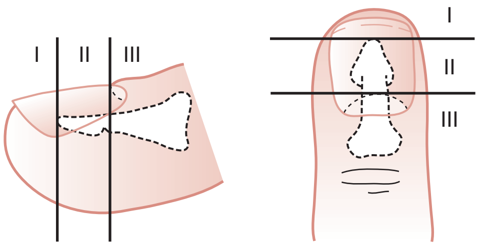

Figure 50-53. Classification of nail bed and fingernail injuries: zone I, distal to the bony phalanx; zone II, distal to lunula (between distal end of lunula and end of phalanx); zone III, proximal to distal end of lunula. (From Rosenthal EA: Treatment of fingertip and nail bed injuries. Orthop Clin North Am 14:675, 1983.)

Management. Treatment of distal fingertip injuries is controversial; consequently, management should be individualized, and few guidelines are available. In general, most hand surgeons try to maintain length of the thumb by whatever means possible.[77] The index finger is considered next before the other fingers. An intact pulp-to-pulp pinch mechanism is the principal goal. Other factors to consider include the patient's age, health, occupation, and handedness.

In most fingertip amputations distal to the DIP joint, adequate care can be provided with conservative wound management. The simplest and often best method for managing a fingertip amputation is allowing the wound to heal by secondary intention. This method generally is effective and produces good results if the wound is less than 1 cm. Large dorsal wounds also heal well by this method. It is the treatment of choice in childhood fingertip amputations, particularly when no bone is exposed. In cases in which a small protuberance of phalangeal bone (extending no more than 0.5 cm) is exposed, it may be trimmed back with a rongeur to just below skin level and the wound allowed to heal by secondary intention; if the bone is left exposed without soft tissue coverage, the patient will need an operative procedure. In most cases the wound heals through a process of granulation, wound contracture, and reepithelialization within a few weeks. Initial management should include careful and meticulous wound cleansing, a nonadherent dressing, appropriate tetanus prophylaxis, and splinting to protect the tip. Amputations that involve the distal phalanx usually are treated as contaminated open fractures with an initial intravenous dose of a cephalosporin followed by an oral course. Patients should have appropriate follow-up care to ensure adequate healing and recovery.

Management of fingertip injuries involving significant soft tissue (especially volar) or bone loss usually requires the expertise of a hand surgeon. Surgical management may include primary closure, full-thickness or partial-thickness skin grafts, composite grafts, adjacent flaps, regional flaps from the hand, distant flaps, and reimplantation. With most of these operative techniques, repair is best performed as a primary procedure under ideal circumstances or as a delayed procedure when necessary. A flap may be used to cover exposed bone or soft tissue avulsion and to add bulk to the tip. The nail bed tissues should be preserved because the presence of a nail affects the cosmetic result. At least 5 mm of healthy nail bed distal to the lunula is needed for nail adherence. Skin grafting is a common method for treating fingertip amputations with significant avulsed tissue and can provide a functional and an esthetic reconstruction.

Complications. These injuries commonly leave the patient with a painful, cold-intolerant fingertip; this complication has been described after primary closure, coverage with grafts or flaps, and healing by secondary intention. Skin grafting may result in induration, fissuring, and diminished sensibility. Nail deformity is common, particularly with considerable volar loss of tissue.[78]

Acute Nail Bed Injuries

Injuries of the nail bed most commonly result from localized trauma to the nail with subsequent compression of the nail bed. The most common type of injury is simple laceration followed by stellate laceration, crush, and avulsion.[79] The middle and distal thirds of the nail bed are the most common sites of injury, and 50% of these injuries involve fractures of the distal phalanx or tuft.[79] Radiographs are required in most cases to show occult fractures and foreign bodies.

Subungual Hematoma. Subungual hematomas result from crush injury or blunt trauma to the nail bed with bleeding from

www.ketabpezeshki.com 66485457-66963820

the rich vascular bed. The nail bed is predisposed to injury because it is interposed between the firm nail and the distal phalanx. The injury is manifested by pain and dark red to black discoloration of the nail bed and is classified by the percentage of area beneath the nail that is involved. When the fingertip is unstable or the mechanism of injury suggests a significant distal phalanx fracture, a radiograph should be obtained to identify associated fracture.

Management. Small subungual hematomas do not require drainage; the blood is incorporated into the nail and eventually removed with the free edge. Large (>50% of the nail) hematomas cause significant discomfort and should be removed by nail trephination with a heated paper clip or a hot microcautery unit. Some clinicians recommend a surgical scrub of the finger before perforation of the nail to prevent contamination of the subungual area and the subsequent risk of infection and potential osteomyelitis, but this generally is unnecessary. Anesthesia is not necessary, and pain relief is immediate with decompression. If a significant fracture is present, the digit should be splinted. Although a distal phalangeal fracture with a subungual hematoma is technically an open fracture, such injuries usually heal without problems. Ungual tuft fractures are not associated with osteomyelitis. The risk of infection with an open fracture of the phalanx proper should be considered, and a broad-spectrum antibiotic and close follow-up monitoring are recommended. Otherwise, antibiotics are not necessary. Patients with significant hematomas should be informed that they may lose the nail.

Some authorities recommend nail removal and nail bed repair if the size of the subungual hematoma is greater than 50% of the nail area. Simon and Wolgin[80] attempted to correlate the association between subungual hematoma size, digital phalanx fractures, and occult nail bed lacerations. In their series, patients with a subungual hematoma greater than half the size of the nail had a 60% incidence of nail bed laceration requiring repair, and if an associated fracture of the distal phalanx was present, the incidence was 95%. If more than 50% of the visible portion of the nail is undermined by hematoma, some clinicians recommend removal of the nail, inspection of the nail bed, and repair of injuries. However, several studies have found no notable differences in outcome between nail trephination alone and formal nail bed repair regardless of hematoma size in cases with an intact nail and nail margins.[81-83] As a result, many authorities now recommend nail removal and repair of the nail bed only if the nail is broken or the nail edges are disrupted.[79]

Nail Bed Lacerations. Lacerations of the nail bed should be repaired to minimize esthetic deformity and the duration of functional impairment. These injuries generally do well after primary repair, but late reconstruction of the nail bed is unpredictable, and usually little improvement is obtained.

Simple and crushing lacerations should be repaired accurately with 5-0 or 6-0 absorbable suture, ideally under loupe magnification. The results with both injuries should be satisfactory in the majority of cases.[79] After the nail bed is accurately approximated, a hole is burned through the nail to allow drainage of blood from the subungual area after the nail is reinserted into the nail fold. The avulsed nail may be sutured in place or secured with tape. A single thickness of nail-shaped Adaptic or other nonadherent gauze may be placed in the nail fold if the nail is unavailable. The replaced nail or gauze is used as a temporary splint to help protect the integrity of the underlying nail bed and maintain the fold for new nail growth and to help prevent synechiae and subsequent nail deformity. Complete nail growth takes 70 to 160 days, but after the injury the growth pattern often is changed.

Nail bed avulsion commonly leaves fragments of nail bed attached to the undersurface of the avulsed nail.[84] In these cases it is advisable to replace the nail as accurately as possible onto the avulsion site. Repair should be done with mattress sutures without attempting to separate the nail from the nail bed. If the tissue is not available and the defect is small, effective healing occurs by secondary intention.

Clenched-Fist Injuries

All human bites should be considered serious in nature and at risk for significant complications. Clenched-fist injuries, also called “fight bites,” are notorious for being the worst human bites. Inadequate initial management leads to significant morbidity. Misleading history, innocuous wound appearance, intoxication and lack of cooperation of the patient leading to inadequate examination, patient reluctance to admit the nature of the injury, delayed presentation, and inadequate exploration all may lead to mismanagement. Clenched-fist injuries are associated with the highest incidence of complications of any closed-fist injury and of any type of bite wound.[85]

Clinical Features

The classic injury is a bite wound over the third MCP joint, but injury can occur over any joint. Soft tissue injury is apparent with possible extensor tendon injury and violation of the joint capsule. When the fist is subsequently opened, the bacterial inoculum is dragged with the extensor tendon and soft tissue proximally into the dorsum of the hand.[85] Presentation may be acute or delayed. Swelling, limited range of motion, erythema, and pain out of proportion to the apparent severity of injury are typical findings. Pain is more severe with range of motion.

Management

Aggressive management is indicated with these injuries. Immediate consultation with a hand surgeon is advised. Analgesics, irrigation, tetanus, cultures, intravenous antibiotics, appropriate wound care, elevation of the affected limb, and hospital admission should be considered for all patients. Foreign bodies are excluded with radiologic studies and possibly exploration. Tendon injuries are ruled out with careful exploration. The hand should be splinted in the position of function. Pathogens usually are polymicrobial, with *Staphylococcus aureus,* streptococci, and anaerobes the predominant species. Multiple-drug regimens are recommended; amoxicillin-clavulanic acid or penicillin with a first-generation cephalosporin is commonly used.

High-Pressure Injection Injuries

Epidemiology

High-pressure injection injuries to the hand are uncommon, and most are occupation related. The usual cause is an accident involving industrial equipment, with machinery such as grease guns, spray guns, and diesel engine injectors accounting for most of these injuries.[86] A wide variety of materials, including paint, paint thinner, grease, oil, hydraulic fluid, plastic, wax, water, and semifluid cement, have been reported to be injected. In general, substances that are highly viscous (e.g., grease) require higher forces to produce injury than do paint, oil, and solvents. The high pressures involved are sufficient to penetrate skin from a distance, and contact of the device with the hand is not a prerequisite for injury to occur. High-pressure injection injuries have been associated with amputation rates as high as 48%.[87] Recent data suggest amputation rates of 30%, which may be a result of higher vigilance and early recognition of tissue injury.[88] Early recognition and intervention are essential. Even with early intervention, the injury leads to significant impairment, with delays in débridement associated with higher rates of amputation.[87]

www.ketabpezeshki.com 66485457-66963820

Pathophysiology

Patient characteristics and injury circumstances often are similar in high-pressure injection injuries. The patient generally has a history of coming into close proximity to the jet stream during cleaning of the nozzle or testing or operation of the equipment. The patient usually is an inexperienced worker, and the nondominant hand most commonly is involved, with the index finger the most common site.

Tissue injury from high-pressure injection generally depends on physical, chemical, and biologic factors. Of particular importance are the type, amount, and velocity of injected material and the anatomic location of the injury. The most important factor is the type of material injected, which determines the likely tissue inflammatory response and the resulting fibrosis that develops during healing. Paint and paint thinner produce a large, early inflammatory response, resulting in a high percentage of amputations.[89] By contrast, grease injuries cause a small inflammatory response and carry a lower amputation rate but are associated with oleogranuloma and fistula formation, scarring, and loss of digit function.[89] The amount of material injected into the confined space of the digits or palm determines the degree of mechanical distention and the potential for vascular compromise. The velocity of the injected material and the site of tissue penetration determine dispersion, which may include the digit, hand, and forearm. Injection injuries at distal sites (e.g., tips of fingers) carry a worse prognosis than proximal injections.[87]

Clinical Features

The patient who seeks treatment early after injury may have minimal symptoms with either an innocuous entrance wound or no visible break in the skin. Fusiform swelling resulting from mechanical distention of the tissue by the injectant may not be apparent. Several hours later, the involved digit or palm becomes extremely painful, swollen, and pale because of vascular compromise and tissue necrosis. Careful examination is necessary to document the extent of injury and associated neurovascular function. Radiographs of the involved hand can help determine the spread of material and the amount of débridement necessary, because certain injected materials are radiopaque. In addition, they may reveal subcutaneous emphysema.

Management

Initial ED management includes splinting, elevation of the affected limb, tetanus prophylaxis, analgesia, and broad-spectrum antibiotics. Digital blocks are contraindicated because of the potential for increased tissue pressure, which may aggravate vascular compromise. The keystone in treatment of these injuries is prompt recognition of the severe nature of the injury despite the often innocuous appearance of the wound. Emergent hand surgery consultation is warranted because most cases require early extensive surgical decompression and débridement.

Complications

Early recognition and treatment, including operative decompression and débridement, greatly influence outcome. Early surgical amputation should be considered in cases in which the affected digit is initially cool or poorly perfused.[90] In most other cases, joint stiffness is a late sequela.

Amputations and Ring Avulsion Injuries

Few epidemiologic studies have been done on amputation injuries. Traumatic amputations have been reported to constitute 0.1 to 1% of all hand injuries.[2] Amputation may be complete or partial. Injuries with interconnecting tissue between the distal and the proximal portions are considered incomplete, or partial, amputations. Complete amputations will necessitate replantation, whereas with partial amputations, revascularization is attempted. Traumatic amputations most commonly result from local crush injuries and occur infrequently from a sharp guillotine mechanism. Partial and complete amputations reportedly occur with equal frequency. The former are often related to the use of power saws and lawnmowers.

Ring avulsions include a spectrum of injuries from partial degloving of the skin of a finger to loss of the entire digit and entire length of a flexor tendon. These injuries usually occur when a ring on a finger catches on an object during a fall. In addition to neurologic and arterial injuries, there may be complete disruption of the venous return of the finger. In general, these injuries represent complex management problems, and treatment may range from primary amputation to microvascular repair with replantation and free tissue transfer in addition to local flap, pedicle flap, or graft coverage.[91]

The initial care and treatment for the patient who has had a body part amputated are the same as for any trauma patient. After the initial primary assessment and stabilization of the patient, the injured extremity should be examined carefully with documentation of neurologic, vascular, and musculotendinous function. Subsequent care should be directed toward preservation of the limb and its components. General management goals include the following: (1) provide supportive care, such as control of hemorrhage with direct pressure and elevation; (2) prolong the time that the amputated tissues remain viable; (3) protect wounds from further injury; and (4) arrange expeditious consultation by a surgical subspecialist. With few exceptions, all completely amputated parts should be considered for replantation, and all partially amputated parts should be considered for revascularization.

In complete amputations, the proximal stump and the amputated part should be examined for degree of tissue injury, contamination, and associated injuries. Gross contaminants can be removed by irrigation with normal saline. Local antiseptics, especially hydrogen peroxide or alcohol, should not be used because they may damage viable tissues. The wound should not be manipulated, clamped, tagged, or traumatized further in any way. The stump should be covered with a saline-moistened sterile dressing to prevent further contamination and desiccation, and the limb should be elevated to help reduce edema and control bleeding. The amputated part requires minimal handling and should be cooled as soon as possible. After being wrapped in saline-moistened gauze, the part is sealed in a dry plastic bag, which is placed in ice water. Ice should not come in direct contact with the tissue because this can cause tissue freezing. Amputated parts should not be discarded or sent to the pathology department because even if they cannot be replanted, they may serve as a donor source for skin, bone, or vessel grafts. Radiographs of the amputated part and proximal stump should be obtained. The use of analgesic medications will likely be necessary, and appropriate tetanus prophylaxis can be administered. The use of prophylactic antibiotics is indicated in amputation injuries because significant devitalized tissue often is present. Most authorities recommend empirical coverage for *S. aureus* with a combination of penicillin G and an antistaphylococcal antibiotic or first-generation cephalosporin.

Treatment for partial amputations with vascular compromise is the same as that just described. The wound should be cleaned with normal saline irrigation, and the injured part wrapped in a sterile moist dressing and splinted to protect it from further injury. Cold packs are applied to the dressings to prevent warm ischemia.

The time for which an amputated part can survive before replantation has not been determined. As a general rule, the more proximal the amputation, the less ischemia time the amputated

www.ketabpezeshki.com 66485457-66963820

part can tolerate. Attempts to extend viability during ischemia have shown that the most important controllable factor is the temperature of the amputated part. Warm ischemia may be tolerated for 6 to 8 hours; cooling the part to 4° C extends this time to approximately 12 to 24 hours with distal amputations. Successful replantation of digits after 40 hours of warm ischemia has been reported.[92]

The decision of whether to attempt replantation should be made by the surgeon who is responsible for performing the procedure. On occasion, final judgment regarding replantation may be delayed until after microscopic inspection of vessels and nerves has been completed.[93] Patient selection generally is based on the nature and level of the injury and patient age and health-related factors. The classic indications for and contraindications to replantation are listed in Box 50-3. The thumb is needed to preserve the function of opposition, and all such traumatic amputations should be considered for microvascular salvage regardless of the level of amputation or mechanism of injury. Loss of the thumb is equivalent to a 40% loss of function of the hand.[94] Similarly, all amputations in children should be considered for replantation. In replantation of digits amputated distal to the insertion of the FDS between the PIP joint and the DIP joint, good motor and sensory function often is achieved. If the amputated part is crushed, mangled, or amputated at multiple levels, however, replantation usually is contraindicated. With digits that cannot be replanted, skin coverage by flaps or ray resection will be required.

Complications

Replanted fingers and hands never regain premorbid function. Replanted and revascularized parts may develop cold intolerance, stiffness, loss of sensation, pain, malunions, and nonunions. Even successful replantations may require repeated operative procedures and involve prolonged disability. Necrosis is an obvious sign of failure.

Vascular Injuries

Significant vascular disorders of the hand are uncommon compared with other problems of the hand. The vascular supply to the hand and digits is duplicated so that isolated arterial injuries to either side seldom result in ischemia. Lacerations of the arteries of the hand may stop bleeding by the time the patient is evaluated; in these situations, a history of pulsatile bleeding is highly suggestive of an arterial injury. Although most arterial injuries are the result of penetrating trauma, blunt trauma to the hand occasionally can result in arterial thrombosis or a false aneurysm.[13] In addition, associated injuries should not be overlooked. Because digital nerves invariably cross with and are superficial to the digital artery, an arterial lesion should raise the possibility of an accompanying nerve injury.

Circulatory status is assessed as previously described by observation for cyanosis or pallor, palpation of radial or ulnar pulses at the wrist, assessment of capillary refill, and the use of Allen's test. Ischemic pain is the most common initial complaint of patients with vascular insufficiency, along with physical manifestations of pallor and gangrene. The presence of a mass, with or without pain and tenderness, is the second most common initial complaint.

Management

Lacerations or amputations of the upper limb rarely cause life-threatening hemorrhage. Even a major vessel that is completely transected usually retracts, constricts, and clots. Major vessels often continue to bleed briskly, however, from partial transections with life-threatening hemorrhage. Usually hemorrhage can be adequately controlled with direct pressure and limb elevation. If necessary, a proximally placed blood pressure cuff inflated to 30 mm Hg above systolic pressure can be used for short periods (<30 minutes) to control severe bleeding. Vascular clamps and hemostats should not be used in the ED to control bleeding in the hand because of the danger of inadvertently crushing nerves and tendons. Lacerated arteries should be repaired if symptoms of ischemia or an associated nerve injury are present. Arterial repair is not mandatory in isolated arterial injuries with good distal vascularity because there is a high rate of thrombosis after reanastomosis. If the decision is made not to repair a lacerated artery, both stumps should be ligated to prevent further bleeding. Palmar arch lacerations may be difficult to visualize in the ED and usually require surgical exploration to control bleeding.

Compartment Syndrome in the Hand

A *compartment syndrome* develops when elevated pressure within a closed fascial space reduces perfusion to the point of muscle and nerve dysfunction. In the hand, 10 compartments are evident on cross section through the palm (Fig. 50-54). In addition, the

Box 50-3 Classic Indications for and Contraindications to Replantation

Indications
- Multiple digits
- Thumb
- Wrist and forearm
- Sharp amputations with minimal to moderate avulsion proximal to the elbow
- Single digits amputated between proximal interphalangeal joint and distal interphalangeal joint (distal to flexor digitorum superficialis insertion)
- All pediatric amputations

Contraindications
- Amputations in unstable patients secondary to other life-threatening injuries
- Multiple-level amputations
- Self-inflicted amputations
- Single-digit amputations proximal to the flexor digitorum superficialis insertion
- Serious underlying disease, such as vascular disease, complicated diabetes mellitus, or congestive heart failure
- Extremes of age

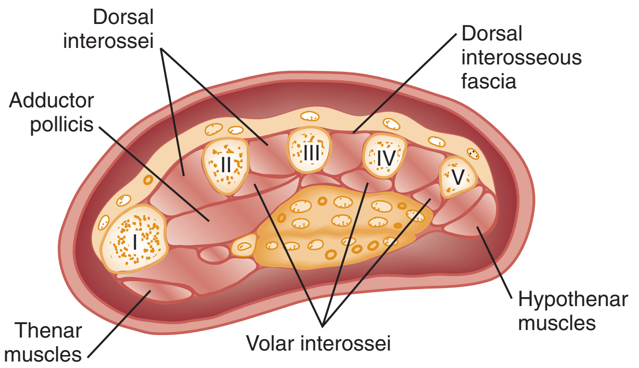

Figure 50-54. Cross section through the palm showing structures involved in forming the compartments of the hand. (From Rowland SA: Fasciotomy: The treatment of compartment syndrome. In Green DP [ed]: Operative Hand Surgery, 3rd ed. New York, Churchill Livingstone, 1993, p 670.)

www.ketabpezeshki.com 66485457-66963820

fingers are compartmentalized by fascia and skin at flexor creases. Because these compartments are not interconnected, each additional compartment should be surgically decompressed if muscle ischemia is suspected.[13,95]

Nerve Injuries

Nerve injuries may result from a direct blow, puncture or laceration, crush injury, injection injury, or amputation. These injuries are divided into three main groups: neurapraxia, axonotmesis, and neurotmesis. In *neurapraxia,* there is loss of function of the nerve, but the axon, Schwann's sheath, and endoneurium remain intact. Recovery in these cases is usually complete within days. In *axonotmesis,* the axon is severed within an intact endoneurial tube. The distal axon degenerates and is absorbed after disruption. The proximal portion of the severed axonal stump can regenerate along the intact endoneurial tube at a rate of approximately 1 to 3 mm/day with ultimate return of function. *Neurotmesis* refers to complete disruption of all nerve elements. Regrowth of the proximal axonal endings does not occur along the endoneurial tubes, unless the severed nerve endings are reapproximated.[96]

Peripheral nerve injuries are diagnosed by physical examination showing loss of motor or sensory function. Specific nerves at risk should be examined as previously outlined. Injury most commonly involves one of the digital nerves but also may be localized to the median, radial, or ulnar nerve.

Management

Identification of the injury and appropriate referral are important aspects in the initial management of patients with nerve injuries in the hand. Patients with closed nerve injuries not associated with compartment syndromes should be referred to a hand specialist for serial examinations. All digits that have lost function as a result of a nerve injury should be splinted to prevent further inadvertent injury. If function does not return within 3 weeks, electromyograms and nerve conduction studies can help differentiate neurotmesis from axonotmesis and determine the need for surgical exploration.[96]

Lacerated nerves require reapproximation by hand surgeons. In general, all motor branches of the ulnar and median nerves should be repaired. In addition, digital nerve injuries proximal to the DIP crease on the radial aspect of the index finger, the ulnar aspect of the little finger, and both sides of the thumb should be considered for repair.[97] Clean, single-nerve lacerations should be repaired primarily when feasible. Complex nerve injuries may involve wound contamination or extensive tissue damage and usually are managed by delayed repair to allow for improved soft tissue conditions. Although the functional recovery is never complete, a good outcome can result from primary and delayed repair. In general, sensory recovery returns more often than does motor function.

Complications

Complications of nerve injuries include motor and sensory loss, atrophy from denervation, chronic paresthesias, regrowth of painful neuromas, and sympathetic dystrophy.

Infections of the Hand

The unique anatomic structures of the hand affect the nature of infections in this region of the body. In general, hand infections can be divided into infections involving the skin, subcutaneous tissues, fascial spaces, tendon, joint, and bone. Fibrous compartments of the distal fingertips contain the spread of infection, whereas flexor tendon sheaths allow infection to travel considerable distances along the lengths of the tendons from the original site. Infections in the deep spaces of the palm usually manifest on the dorsal surface of the hand.

Paronychia

Pathophysiology. A *paronychia* is a localized superficial infection or abscess involving the lateral nail fold. It is the most common infection in the hand and is thought to be caused by frequent trauma to the delicate skin around the fingernail and cuticle. Clinically, swelling and tenderness of the soft tissue along one or both sides of the lateral nail fold are evident. A paronychia begins as a cellulitis, but a frank abscess may form, and occasional extension to the overlying proximal nail (termed an *eponychia*) may be seen. *S. aureus* is the most common isolate, followed by streptococci.[98] Paronychias in children often are caused by anaerobes, presumably because of finger sucking and nail biting common in this age group.[99] Atypical mycobacteria, *Candida albicans,* and other fungi should be considered as causative agents in chronic cases unresponsive to standard treatment.[100]

Management. In the early cellulitis phase, management consists of frequent warm soaks, elevation of the affected limb, and administration of an oral antistaphylococcal antibiotic, such as dicloxacillin or cephalexin. When the area becomes fluctuant, drainage is necessary and usually is curative. Adequate drainage often can be obtained by lifting the skin edge off the nail to allow the pus to drain (Fig. 50-55). This can be accomplished without anesthesia in selected patients, but drainage for more extensive lesions is best carried out under digital block anesthesia. After the eponychium has been softened by soaking, a No. 11 blade scalpel or an 18-gauge needle may be advanced parallel to the nail and under the eponychium at the site of maximal swelling.[98] If the infection is more extensive, the lateral one fourth of the nail may be bluntly dissected from the underlying nail bed and germinal matrix, and the lateral nail plate excised. After the cavity is irrigated, a small piece of packing gauze may be slipped under the eponychium for 24 hours to provide continual drainage. Cultures are not indicated. Antibiotics are commonly prescribed, although this is not necessary if drainage is complete or if the surrounding area of cellulitis is minimal. Most paronychias resolve in 5 to 10 days, and patients are advised to obtain primary care follow-up evaluation. A well-known complication of even a properly drained paronychia is osteomyelitis of the distal phalanx. Patients with a chronic,

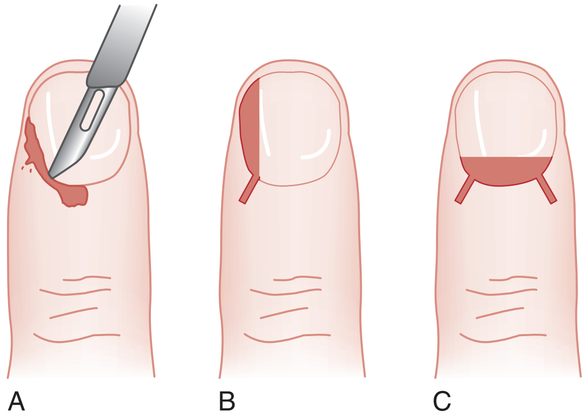

Figure 50-55. Drainage of paronychia. **A,** Eponychial fold is elevated from the nail for a simple paronychium. **B,** Lateral nail is removed if pus tracks under it. A small eponychial incision may be necessary. **C,** Proximal nail is removed if pus tracks under it. Two incisions are needed to remove the proximal nail. (From Moran GJ, Talan DA: Hand infections. Emerg Med Clin North Am 11:601, 1993.)

www.ketabpezeshki.com 66485457-66963820

indolent infection of the perionychium seldom respond to ED intervention. These patients should be referred to a dermatologist or hand surgeon because of the prolonged treatment required.

Felon

Pathophysiology. A *felon* is an infection of the pulp of the distal finger or thumb. It differs from other types of subcutaneous abscesses because of the presence of multiple vertical septa that divide the pulp into small fascial compartments. The usual cause is penetrating trauma with secondary bacterial invasion. The most common pathogen is *S. aureus,* although gram-negative organisms and polymicrobial infections also have been described.[100] Although the septa may facilitate an infection in the pulp and inhibit drainage after incomplete surgical decompression, they provide a barrier that protects the joint space and the tendon sheath by limiting the proximal spread of infection. Clinically, a felon begins as an area of cellulitis and inflammation that progresses rapidly to severe throbbing, pain, swelling, and increased pressure in the distal pulp space.

Management. Traditional management of felons emphasizes the need for early and complete incision through the septa to provide adequate drainage and to relieve pressure in septal compartments. Most felons can be drained by a single lateral incision.[100] The incision should be made along the ulnar aspect of the index, middle, and ring fingers and the radial aspects of the thumb and little finger, avoiding pincher surfaces. The incision is begun approximately 0.5 cm distal to the DIP joint crease and dorsal to the neurovascular bundle of the fingertip. The incision is extended to the free edge of the nail (Fig. 50-56). The wound should be irrigated and loosely packed with gauze, and the affected finger splinted. The packing is removed in 48 to 72 hours, and the wound is left to close secondarily. Most felons are treated empirically with an antistaphylococcal oral antibiotic for at least 5 days pending culture results. Some authorities recommend draining this abscess where it "points," with use of a volar midline incision that does not cross the distal flexion crease.[101]

Complications. If untreated, the expanding abscess can extend toward the phalanx, producing an osteitis or osteomyelitis, or toward the skin, resulting in necrosis and formation of a sinus tract on the palmar surface of the digital pulp. Other complications include soft tissue and bony tuft necrosis, osteomyelitis, septic arthritis of the DIP joint, and flexor tenosynovitis from proximal extension. The lateral incision used to drain felons commonly leaves unstable finger pads or may result in painful neuromas or anesthetic fingertips. "Fishmouth" incisions may destroy the blood supply to the fingertip.[100] Longitudinal midline incisions on the volar surface may leave scars over an important area for sensation but do not have the other disadvantages of lateral incisions. Any incision that is made too deeply and proximally can injure the flexor tendon sheath, initiating a tenosynovitis.

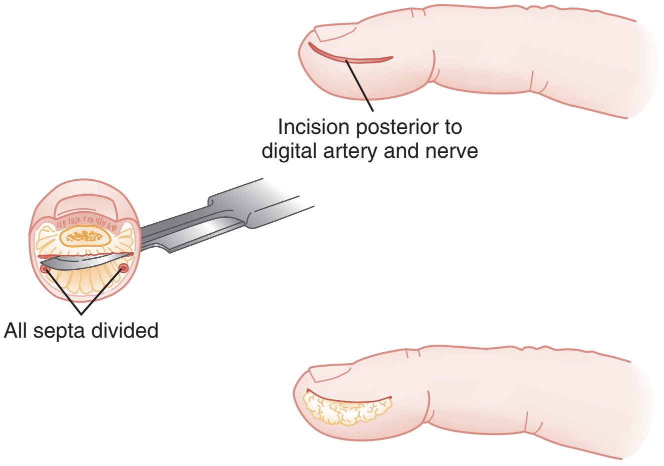

Figure 50-56. Incision and drainage of felon with the unilateral longitudinal approach. Most felons should be drained via this incision. (From Wright PE: Hand infections. In Canale ST [ed]: Campbell's Operative Orthopaedics, 11th ed. St. Louis, Mosby, 2008.)

Herpetic Whitlow

Epidemiology and Pathophysiology. Herpetic whitlow is a self-limited herpes simplex viral infection of the distal finger. It is the most common viral infection of the hand. Infection by human herpes simplex virus type 1 or 2 is clinically indistinguishable.[102] Direct inoculation of the virus into an open wound or broken skin is the usual mechanism of primary infection. Herpetic whitlow commonly is reported in adult women with genital herpes and children with coexistent herpetic gingivostomatitis. Health care workers are at increased risk for development of this infection as an occupational hazard secondary to exposure to orotracheal secretions; however, a review of herpes infection in the hand found that only 14% of adult cases occur in health care workers.[103] The overall incidence has decreased, probably as a result of heightened awareness of the condition and strict infection control precautions.

Clinical Features. The infection usually involves a single finger and begins with localized pain, pruritus, and swelling, followed by the appearance of clear vesicles. Systemic symptoms usually are absent; however, secondary infection of the vesicles can occur.[102] More typically, the vesicles coalesce over 2 weeks to form an ulcer, which may develop a hemorrhagic base. At this stage, it may be difficult to distinguish herpes simplex infection of the hand from more common bacterial infections, such as felon or paronychia. The distinction is important because drainage of the herpetic lesions is contraindicated and may lead to viral dissemination and secondary bacterial infection. A careful history is important to determine risk of a possible herpetic cause. On examination, tenderness is present but is noticeably less than that typical for bacterial infections. In addition, the pulp space remains soft and does not become tense, as it does in a bacterial felon.[104]

Diagnostic Strategies. The diagnosis usually is made clinically on the basis of the appearance of the lesion and the history of recurrence or potential sources of inoculation. The diagnosis may be confirmed by polymerase chain reaction (PCR), viral culture, or a Tzanck smear showing multinucleated giant cells in a scraping taken from the base of an unroofed vesicle.[102,105]

Management. Herpetic whitlow usually resolves spontaneously in 3 to 4 weeks, although recurrence is common, occurring in up to 20% of cases. The main goals of treatment are to prevent oral inoculation or transmission of the infection and to provide symptomatic relief. The involved digit should be kept covered with a dry dressing. Oral acyclovir has a role in treatment for immunocompromised patients and patients with frequently recurring infections, but its role in immunocompetent patients is less clear.[105] Topical acyclovir has not been shown to be effective in either the treatment of or the prophylaxis for this disorder.

Tenosynovitis

Pathophysiology. Acute synovial space infections in the hand usually involve the flexor tendon sheaths and the radial and ulnar bursae. The tendon sheaths are double-walled, with a visceral layer adherent to the tendon and a parietal layer extending from the midpalmar crease to just proximal to the DIP joint. The flexor tendon sheath of the thumb is continuous with the radial bursa of the palm, and the small finger sheath is continuous with the

www.ketabpezeshki.com 66485457-66963820

ulnar palmar bursae. The ulnar bursa surrounds the superficial and deep flexor tendons, and the radial bursa surrounds the flexor pollicis longus. These two bursae communicate in 80% of persons; in most instances, however, the tenosynovial coverings of the index, middle, and ring fingers do not communicate. Infections in the synovial spaces in the hand tend to spread along the course of the flexor tendon sheaths and may spread to the midpalmar, thenar, and lumbrical compartments. Infections usually are caused by penetrating trauma to the sheath, but they occasionally result from hematogenous spread. The most commonly isolated organisms are *S. aureus* and streptococci, followed by gram-negative organisms and enterococci.[106]

Clinical Features. Four cardinal signs of acute flexor tenosynovitis usually are present and help differentiate tenosynovitis from other soft tissue infections in the hand: (1) tenderness along the course of the flexor tendon, (2) symmetrical swelling of the finger, (3) pain on passive extension, and (4) a flexed posture of the finger.[60] All four signs may not be present early in the course of infection. The third sign may be the most important. Early recognition and treatment are essential because elevated pressure within the enclosure of the flexor tendon sheath can occlude the already tenuous circulation to the tendon, resulting in necrosis and proximal spread.

Management. All patients with flexor tenosynovitis require hospital admission and prompt consultation with a hand surgeon to determine whether open drainage or closed tendon sheath irrigation is indicated. In early cases or uncertain diagnoses, the hand should be splinted in a bulky dressing and elevated, and intravenous antibiotics should be initiated. Infections secondary to penetrating trauma should be treated with a penicillinase-resistant antistaphylococcal penicillin or first-generation cephalosporin. Disseminated gonorrhea should be considered in all sexually active persons, especially if a traumatic cause for the infection is not apparent. In such cases, some authorities recommend empirical treatment with ceftriaxone until results of final cultures (including mucosal sites) are available.[106,107] Surgical treatment is indicated for established cases or when improvement is not evident within 24 hours.

Deep Space Infections

Anatomy and Pathophysiology. The deep fascial or palmar spaces of the hand include the midpalmar space, the hypothenar space, and the thenar space. Three additional, more superficial spaces of the hand are the dorsal subcutaneous space, the dorsal subaponeurotic space, and the interdigital web space[108] (Fig. 50-57). Although anatomically distinct from the deep spaces owing to their lack of well-defined anatomic borders, superficial spaces can harbor infections that manifest similarly to deep space infections.[108] The fascial spaces are potential rather than actual spaces in a normal hand.[109] These closed compartments are susceptible to infection from direct penetrating trauma, infection in contiguous compartments, or hematogenous seeding. The most commonly isolated pathogens are *S. aureus*, streptococci, and coliforms.

Clinical Features. The unique anatomic features of the deep fascial spaces lead to characteristic clinical findings when these regions are involved with pyogenic infection. The dorsal subaponeurotic abscess causes swelling and erythema on the dorsum of the hand. Pain with passive movement of the extensor tendons often is present, but it may be difficult to distinguish clinically from simple cellulitis on the dorsum of the hand. Subfascial web space infections commonly result when palmar blisters become secondarily infected. The infection tends to spread dorsally into the interdigital space and produce a characteristic hourglass configuration, or the so-called "collar-button abscess" (Fig. 50-58). Thenar space infections are characterized by pain and swelling of the thenar eminence and the first web space; the thumb is held in abducted and flexed position.[109] In midpalmar infections, clinical features include loss of the normal hand concavity and tenderness of the central palm; movement of the middle and ring fingers is painful. Suppurative tenosynovitis of the second digit can rupture proximally into the thenar space, with subsequent abscess formation. Tenosynovitis of digits III, IV, and V may be responsible for a midpalmar space infection.

Management. Treatment of all deep fascial space infections involves intravenous antibiotics and operative exploration and drainage by experienced surgeons. The most common practice is to use broad-spectrum empirical coverage with a β-lactamase–resistant penicillin or a first-generation cephalosporin. Based on local bacteriologic data, it may be necessary to begin empirical coverage against methicillin-resistant *S. aureus* (MRSA).[110]

www.ketabpezeshki.com 66485457-66963820

Septic Arthritis

Pathophysiology. Septic arthritis in the hand may involve the IP, MCP, CMC, or radiocarpal joints. These joints usually are infected by direct inoculation of bacteria from penetrating trauma or by spread from a contiguous infective process, such as a felon or tenosynovitis. Hematogenous spread may occur but is less common than in other joints of the body. *S. aureus* is the most common cause; streptococci, *Haemophilus influenzae, Pseudomonas aeruginosa,* and coliforms are involved much less commonly.[111] A survey at a large county hospital found that the most commonly isolated organisms were staphylococci and streptococci in nearly equal numbers, with enterococci, corynebacteria, and anaerobes encountered rarely.[112] Monarticular nontraumatic septic arthritis also may be caused by *Neisseria gonorrhoeae.*

Clinical Features. Clinically the involved joint appears red and swollen and is extremely tender; an overlying puncture wound may be visible. The joint is held in a position that maximizes its volume (slight flexion for MCP and IP joints), and passive motion of the joint, however slight, is painful. In contrast with flexor tenosynovitis, tenderness is localized to the involved joint.[108] Pain also may be elicited by axial compression of the joint. The diagnosis is made by arthrocentesis.

Management. Treatment includes parenteral antibiotics with a semisynthetic antistaphylococcal penicillin and emergent drainage of the joint. Most infected joints require open drainage, but some hand surgeons may choose to manage certain cases with closed joint catheter irrigation and repeated aspiration.

Osteomyelitis

Osteomyelitis in the hand occurs most commonly with open fractures or with secondary involvement of bone from soft tissue infections. The incidence of infection in open fractures of the hand is much lower than in open long bone fractures and is reported to be 1 to 11%. McLain and colleagues[30] found that injuries with severe skeletal trauma, gross contamination, and significant soft tissue injury have the highest risks for infection. The presentation of osteomyelitis is seldom rapid and fulminant, unless associated with septic arthritis or other deep space infection of the hand. Physical signs may include fever, localized redness, swelling, warmth, and tenderness. Children with osteomyelitis may have pseudoparalysis, manifesting as refusal to use the affected limb.[114] Radiographs may show bone destruction or periosteal elevation. Treatment includes débridement of infected bone and sequestra and parenteral antibiotics.

Nontraumatic Disorders of the Hand

Stenosing Tenosynovitis

The most common type of stenosing tenosynovitis in the hand involves the flexor tendons at the level of the MCP joint where the tendon passes through the pulley systems. Repetitive strain can result in tendon and pulley hypertrophy with localized tenderness. When painful blocking of flexion and extension is noted at the involved joint, the condition is called *trigger finger,* as noted earlier. The ring and long fingers are the most commonly involved digits. Injection therapy is recommended and works well in most patients.[115] A mixture of 1% lidocaine and steroid suspension (for a total volume of 0.5-1 mL) is given over the nodule and into the tendon sheath.[116,117] After the injection, extension of the finger usually is possible. The finger should be splinted in extension, and referral to a hand surgeon is advised because multiple injections or surgical release may be required.[118]

Ganglion

A ganglion is the most common soft tissue tumor of the hand and consists of a synovial cyst from either a joint or the synovial lining of a tendon that has herniated. Ganglia contain a gelatinous fluid that is secreted by the synovial tissue. They are common in the wrist and the flexor tendon sheaths of the fingers and usually have an insidious onset. Patients rarely recall a specific inciting traumatic event.[119] Patients commonly complain of a dull ache or mild pain over the ganglion. Reassurance is important, and the patient should be informed of the benign nature of the lesion. A large or troublesome ganglion can be aspirated. Because of the high rate of recurrence, definitive treatment is operative excision, which is done on an elective basis.[119]

Foreign Bodies in the Hand

Penetrating trauma to the hand may result in a foreign body becoming lodged in the soft tissues. The presence of a foreign body should be considered in any wound regardless of its size. A detailed and accurate history of the injury should be obtained because the mechanism often gives clues to the possibility of a foreign body.[120] The most common foreign bodies are pieces of wood, glass, or metal. Useful signs of occult foreign bodies include sharp pain with deep palpation over a puncture wound, pain associated with a mass, and failure of a wound to heal or persistence of pain with movement.[19]

Initial examination of hand wounds should include local exploration with sterile technique in a bloodless field. After exploration and removal of easily accessible foreign bodies, radiographs should be taken using soft tissue technique with multiple views. Radiographs are the best method for detecting radiopaque foreign bodies and detect metals, most glass, many plastics, gravel, and sand.[19] Wooden foreign bodies are difficult to visualize radiographically.[121] Whether an object shows on plain radiographs depends on its composition, configuration, size, and orientation. When a foreign body is clinically suspected and the initial radiographic appearance is normal, other imaging methods should be considered. The identification of nonmetallic objects such as splinters may be improved by the use of modalities including computed tomography, magnetic resonance imaging, and ultrasound studies.[19,121,122]

Management

Removal of embedded foreign bodies can be difficult and time-consuming, and potential damage to tissues caused by the procedure is weighed against the risk posed by the specific foreign body. Generally, if a foreign body contaminating a wound is clearly visible and likely to be easily extractable during local exploration, it should be removed in the ED. In some cases, the entrance wound may need to be enlarged with a small skin incision. In general, foreign bodies should be removed only under direct vision. When the object is buried within the intricate anatomy of the hand, this procedure should be deferred to a hand specialist.

Decisions regarding the necessity and timeliness of removal of a foreign body are based on the size and the reactivity of the foreign body, proximity to vital structures, degree of wound contamination, and presence or absence of symptoms.[19] Foreign bodies that cause continued pain, interfere with hand function because of their size or their position, or cause local or systemic toxicity (e.g., paints or mercury) should be removed. In removing foreign bodies, traction should be applied along the long axis of the foreign body in order to allow easier extraction, as well as to avoid breakage into two or more pieces. With foreign bodies

www.ketabpezeshki.com 66485457-66963820

associated with fractures, prompt surgical débridement is necessary to prevent osteomyelitis.[123] Wounds that are grossly contaminated with soil or organic material require immediate removal of the foreign body, débridement, and irrigation. Foreign bodies near tendons, nerves, and vessels and foreign bodies causing ischemia or hemorrhage require cautious removal under optimal conditions.

Patients who do not require immediate removal of the foreign body may be referred to a hand surgeon for delayed surgical exploration. If the hand specialist plans to remove the object within 3 to 4 days after injury, and if bacterial contamination is minimal, the wound may be closed primarily. Initial treatment also should include tetanus prophylaxis and an appropriate wound dressing. The patient should be informed about the presence of the foreign body and the reason for delayed removal. If no removal is planned, the physician should explain to the patient that the dangers of removal outweigh the benefits.

Complications.

Foreign bodies can damage soft tissues, provoke excessive inflammation with granuloma formation, predispose the patient to infection, and cause systemic toxicity. Iatrogenic damage to tissue can result from blind probing or excessively aggressive searches for foreign bodies; such maneuvers should be avoided, particularly in the hand.

KEY CONCEPTS

- Injuries and infections of the hand are among the most commonly encountered problems in the ED.
- An accurate history and carefully performed physical examination of the hand have a central role in evaluation and treatment. Hand radiographs should be obtained if suggestive signs are present. High-technology diagnostic modalities are rarely indicated.
- The best functional outcomes of hand injuries usually are achieved by accurate initial evaluation and treatment.
- A key factor in the evaluation of hand injuries is determining which entities require specialty referral or urgent consultation.
- Management of the injured hand should focus on restoring function and minimizing long-term disability.

Chapter 51

Wrist and Forearm

David T. Williams and Hyung T. Kim

WRIST

PERSPECTIVE

The wrist joint is broadly defined as the anatomic area from the distal radius and ulna bones of the forearm to the carpometacarpal junctions of the hand. It is anatomically and biomechanically complex, allowing for diverse functional capabilities. In the setting of trauma, this area is exposed, mobile, and at high risk of injury. Detailed knowledge of relevant anatomy, mechanism of injury, accurate clinical assessment, and radiograph interpretation are essential for proper emergent diagnosis and treatment.

Anatomy

The wrist is composed of many complex articulations, including the radiocarpal, midcarpal and distal radial ulnar joints (DRUJs), allowing for flexion, extension, abduction (radial deviation), adduction (ulnar deviation), and circumduction movements. Pronation and supination of the hand are primarily movements of the forearm occurring at the proximal and DRUJs.

The wrist includes the distal radius, ulna, and eight carpal bones, which are arranged in two transverse rows and commonly referred to as the *carpus* (Fig. 51-1). Each carpal row contains four bones. The more mobile, proximal row, listed radial to ulnar, consists of the scaphoid, lunate, triquetrum, and pisiform, whereas the distal row consists of the trapezium, trapezoid, capitate, and hamate bones.

The radius has three articular surfaces at the wrist: the radiocarpal joint, the DRUJ, and an interface with the triangular fibrocartilage complex (TFCC), also known as the *articular disk*. Only the distal radius articulates directly with the carpus via the scaphoid and lunate bones, forming the radiographic joint, commonly referred to as the "wrist joint." The ulna is separated from direct articulation with the proximal carpal row by the TFCC. This articular disk binds the distal ends of the radius, ulna, lunate, and triquetrum together. The DRUJ is a synovial pivot where the distal radius articulates and rotates around the relatively fixed ulna, and this joint is primarily stabilized by the TFCC.

Aside from the pisiform, which is considered to be a sesamoid bone embedded within the flexor carpi ulnaris (FCU) tendon, the carpus bones are lined by synovium that creates a continuous capsule throughout the intercarpal joints and distally to the metacarpal articulations. The only muscular insertions that occur throughout the carpus are the origin of the abductor digiti minimi from the pisiform and the point at which the FCU tendon inserts onto the hook of the hamate. As a result, nearly all carpal bone movements are passive based on muscular insertions on the distal radius, ulna, and metacarpal bases.

The stabilizing ligaments of the wrist joint are divided into two major groups: the intrinsic ligaments and the extrinsic ligaments. The *intrinsic* ligaments interconnect the individual carpal bones, and the *extrinsic* ligaments link the carpal bones to the distal radius, the ulna, and the metacarpals. The intrinsics are named for the adjacent bones they connect, and the most important for maintaining carpal stability are the scapholunate and lunotriquetral ligaments. The extrinsics are divided into a volar and dorsal group. The volar extrinsic ligaments are divided into two V-shaped ligamentous bands called the *proximal* and *distal arcades*, which generally are thicker and stronger than the dorsal extrinsic ligaments and are the most important in providing stability to the wrist. Between these volar arcades is an area relatively devoid of ligamentous support called the *space of Poirier*. This space enlarges when the wrist is dorsiflexed, and an injury to the joint capsule in this region can result in significant carpal instability (Fig. 51-2).

Most structures that cross the wrist joint are contained within individual compartments formed by the deep fascia of the wrist. On the dorsal surface of the wrist, the extensor tendons are divided by the extensor retinaculum into six compartments, each having a separate synovial sheath that extends proximal and distal to the retinaculum. On the volar surface of the wrist, the flexors of the digits and the median nerve are contained within the carpal tunnel, which is formed by the flexor retinaculum superficially and its attachments to the carpal bones. Radially, the flexor retinaculum attaches to the scaphoid tubercle and the ridge of the trapezium. On the ulnar side, it attaches to the pisiform and the hook of the hamate. The floor of the carpal tunnel is formed by both the trapezoid and capitate bones. Radial and superficial to the carpal tunnel, the flexor carpi radialis tendon crosses the wrist joint in its own compartment.

The vascular supply to the wrist is provided by the radial and ulnar arteries, which join in a series of dorsal and palmar arches to supply the bones of the carpus. The intrinsic blood supply to most carpal bones enters the distal portion of the bone, leaving the proximal portion at risk for devascularization and avascular necrosis (AVN) when fractured. This is particularly true for the scaphoid, capitate, and lunate, because they each receive their blood supply from a single distal vessel (Fig. 51-3).

The innervation of the wrist and hand is by the radial, median, and ulnar nerves. The radial nerve and the dorsal sensory branch of the ulnar nerve cross the dorsum of the wrist near the radial and ulnar styloids, respectively. The median nerve crosses within the carpal tunnel on the volar aspect of the wrist just radial and deep to the palmaris longus tendon. The ulnar nerve is within Guyon's canal between the pisiform and the hook of the hamate (see Fig. 51-3). In the setting of trauma, motor and sensory function of the radial, median, and ulnar nerves may be assessed

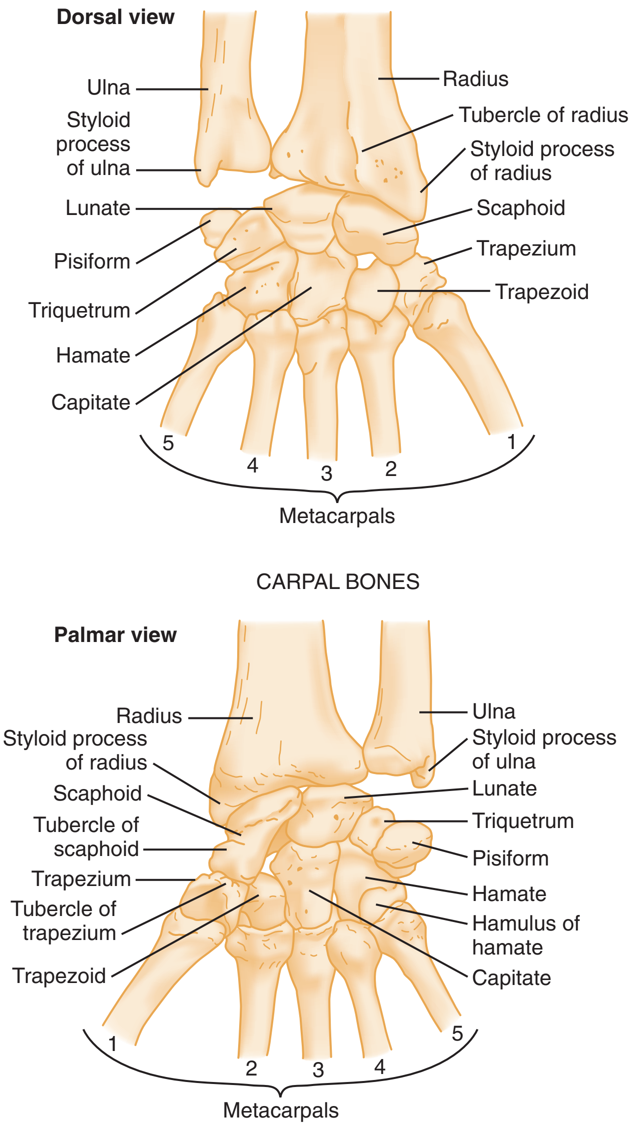

Figure 51-1. Bones of the wrist. The wrist joint includes the distal articular surfaces of the radius and ulna and the proximal and distal carpal rows. (Redrawn from Netter FH: Atlas of Human Anatomy, 3rd ed. Teterboro, NJ, Icon, 2003.)

at the wrist and distally based on common clinical examinations (Table 51-1).

CLINICAL FEATURES

The clinical examination of the patient with a wrist injury begins with a complete history, including the mechanism of injury and the site of maximal pain or tenderness. Most wrist injuries are caused by a fall on the outstretched hand. The physical examination begins with inspection of the wrist, with the opposite uninjured wrist used as the "normal" reference, and includes an assessment of the presence of swelling, discoloration, or obvious deformity and the ability of the patient to move the joint through a normal range of motion.

On palpation, several bony prominences serve as useful landmarks, and the locations of these are best described in relation to the two major lateral and medial reference points in the wrist, the radial and ulnar styloids, respectively. Just distal to the radial styloid is the anatomic snuffbox, bordered radially by the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons and ulnarly by the extensor pollicis longus tendon. The body of the scaphoid is palpable within the snuffbox and is more prominent with the wrist in ulnar deviation.[1] Lister's tubercle can be palpated on the dorsum of the wrist just ulnar to the radial styloid. This is an important landmark because, notably, just distal to the tubercle lies the scapholunate joint, a common site of ligamentous injury in the wrist. With the wrist in neutral position, the capitate is palpable in a small depression found midway between the base of the middle metacarpal and Lister's tubercle. Bringing the wrist into flexion can bring the lunate forward into a palpable position at this same site. Lister's tubercle divides the second and third dorsal extensor compartments of the wrist and is also used as a primary landmark for radiocarpal arthrocentesis. Further ulnar on the dorsal side of the wrist from Lister's tubercle is the DRUJ. The triquetrum is palpable just distal to the ulnar styloid in the proximal carpal row and can be made more prominent with radial deviation of the wrist.

On the volar aspect of the wrist, the scaphoid tubercle is palpable just distal and palmar to the radial styloid. It is felt as a rounded prominence at the base of the thenar muscles and is especially prominent when the wrist is extended. On the ulnar border of the wrist, the pisiform is palpable at the base of the hypothenar muscles, just distal to the distal wrist crease. In addition, approximately 1 cm distal and radial to this point, the prominence formed by the hook of the hamate can be palpated.

The clinical examination also includes an assessment of the neurovascular status. Radial and ulnar pulses are easily palpable on the volar surface of the wrist, and the presence of pulses should be evaluated in all injuries to the wrist.

DIAGNOSTIC STRATEGIES: RADIOLOGY

Plain radiographs remain the cornerstone of emergent diagnosis of fractures and dislocations of the wrist. Routine radiographic views include the posteroanterior (PA), lateral, and oblique projections, each obtained with the wrist in neutral position. Accurate interpretation of these views requires knowledge of the normal appearance and anatomic relationships of the distal radius, ulna, and carpal bones.

On a correctly positioned PA view of the wrist, the ulnar styloid arises from the lateral aspect of the distal ulna, and the extensor carpi ulnaris (ECU) tendon groove should be visualized at, or radial to, its base. The radial styloid process extends beyond the end of the articular surface of the ulna by a normal distance of 9 to 12 mm. This normal difference in length is called the *radial length measurement* (Fig. 51-4). There may be some degree of *ulnar variance* that affects the radial length measurement on a PA radiograph. The distal articular surface of the ulna may terminate before, at, or distal to the radiolunate articulation as a result of wrist rotation, flexion, extension, anatomic variation, or injury. Neutral ulnar variance (as seen in Fig. 51-4) is described when both the distal ulnar and radiolunate articular surfaces terminate at the same point distally. A positive ulnar variance (ulnar articulation is more distal) or negative ulnar variance (ulnar articulation is more distal) or negative ulnar variance (ulnar articulation is more proximal) is independent of styloid size and may be associated with wrist pathology (e.g., ulnar impaction syndrome and Kienbock's disease, respectively). The ulnar slant of the articular surface of the radius, referred to as *radial inclination,* is visible on the PA view and normally measures 15 to 25 degrees (see Fig. 51-4). Both of these measurements are important in assessing the degree of radial shortening seen in association with some fractures of the distal radius.[2] The normal appearance of the carpus on the PA view shows an approximately equal distance (usually 1 to 2 mm) between each of the carpal bones, and opposing articular surfaces are parallel to one another (an arrangement known as *parallelism*). On radiographs, three smooth curves normally can

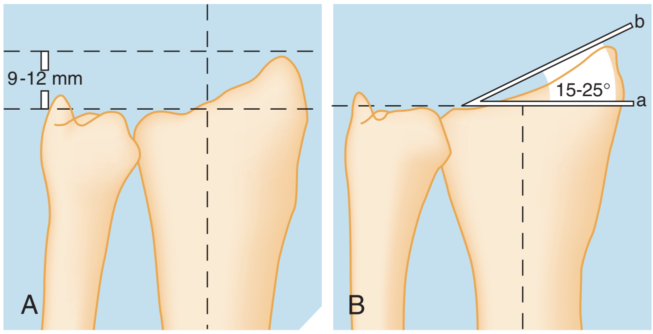

Figure 51-4. Normal radiographic appearance of the wrist on a posteroanterior view. The ulnar styloid arises from the lateral aspect of the distal ulna, and the tendon groove for the extensor carpi ulnaris should be visualized at, or radial to, its base. **A,** Radial length measurement with neutral ulnar variance. The radial styloid extends 9 to 12 mm beyond the articular surface of the distal ulna. The ulna may terminate distal, at, or proximal to the radiolunate articulation affecting radial length measurement with a positive, neutral, or negative variance, respectively. **B,** The ulnar slant of the distal radius normally measures 15 to 25 degrees. (From Greenspan A: Orthopedic Radiology: A Practical Approach, 2nd ed. New York, Gower Medical Publishing, 1992.)

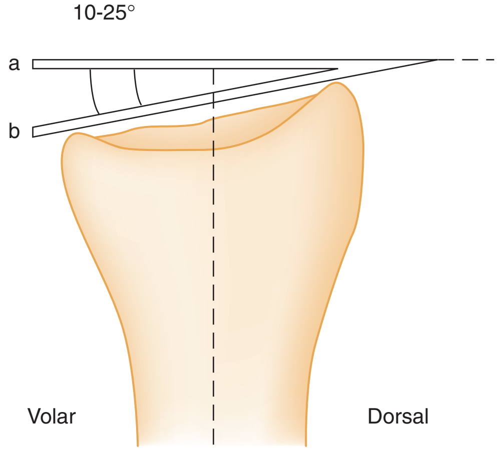

Figure 51-6. Normal radiographic appearance of the wrist on a lateral view. The distal radius has a normal volar tilt of 10 to 25 degrees. (From Greenspan A: Orthopedic Radiology: A Practical Approach, 2nd ed. New York, Gower Medical Publishing, 1992.)

Figure 51-5. Carpal (Gilula's) arcs. On a posteroanterior radiograph of the wrist, three arcuate lines (*1* to *3*) can be drawn along the articular surfaces. Although small indentations at joint lines may occur, a step-off or "broken arc" suggests fracture, ligamentous instability, or disruption of the wrist.

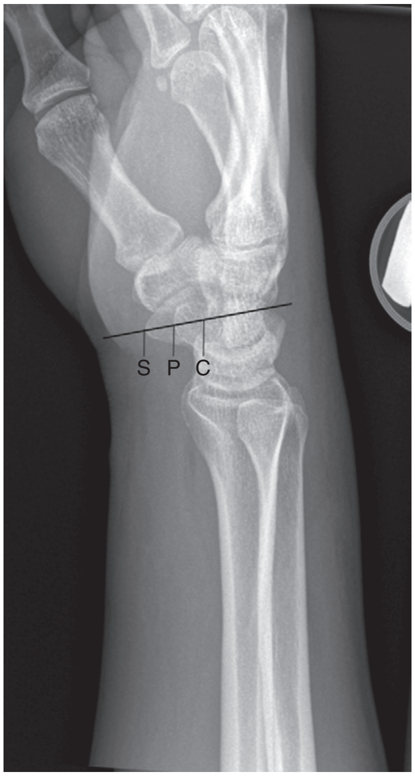

Figure 51-7. Normal S-P-C (scaphoid-pisiform-capitate) lateral view of the wrist. The palmar cortex of the pisiform *(P)* is shown bisecting the line between the palmar aspect of the scaphoid *(S)* and capitate *(C)* bones.

be drawn along the carpal articular surfaces, known as *carpal* or *Gilula's arcs* (Fig. 51-5). Disruption of these curves or widening of the carpal spaces is an indication of carpal ligament disruption, instability, or fracture.[3]

The normal volar tilt of the distal radial articular surface is visible on the lateral view of the wrist and normally measures 10 to 25 degrees (Fig. 51-6). Adequacy of a lateral view of the wrist is assessed based on the relationship among the scaphoid, pisiform, and capitate projections. The palmar cortex of the pisiform should project midway between the palmar margins of the distal pole of the scaphoid and the capitate head, forming the S-P-C lateral (Fig. 51-7). The normal alignment of the distal radius with the lunate and capitate also is seen on the lateral view, which will show two concentric cups, the cup of the distal radius containing the lunate and the cup of the distal lunate containing the capitate. Ideally, the long axis of the radius, lunate, capitate, and third metacarpal should appear as a straight line on the lateral view, although the "normal" alignment usually is within 10 degrees of this line (Fig. 51-8). The carpal alignment on the lateral view is defined further by the scapholunate angle, which normally

www.ketabpezeshki.com 66485457-66963820

measures 30 to 60 degrees, and the capitolunate angle, which normally is 0 to 30 degrees (Fig. 51-9). Abnormalities in these angles are seen in patients with carpal ligament injuries and carpal instability.

The soft tissues of the wrist also offer valuable clues to the presence of underlying bony injuries. It is estimated that on 90% of normal lateral radiographs of the wrist, the pronator quadratus line is visible as a linear, lucent, fat collection in the volar soft tissues just anterior to the distal radius and ulna (Fig. 51-10). Fractures of the distal radius or the ulna result in volar displacement, anterior bowing, or complete obliteration of this line. Although this pronator quadratus sign may suggest fracture, a wide range of sensitivities has been quoted—26 to 98%—so its absence does not exclude a fracture. A positive pronator quadratus sign has also been observed in soft tissue injuries and infectious and inflammatory medical conditions.[4]

Additional radiographic imaging of the wrist may be indicated based on chief complaint, mechanism of injury, or physical examination findings, including specific areas of tenderness. In addition to the standard PA, lateral and oblique wrist radiographs, adjunct imaging may include views with ulnar and radial deviation, maximal flexion, extension, a carpal tunnel view, reverse (supinated) oblique, clenched fist PA, or anteroposterior (AP) views. Patient-specific imaging helps to further delineate otherwise occult fracture or abnormal motion of the carpus resulting from ligamentous injuries. Specific scaphoid views, obtained with the wrist pronated and in ulnar deviation, allow for better visualization of the scaphoid along its long axis. The carpal tunnel view is performed with the wrist hyperextended and provides an axial image of the bony margins of the carpal tunnel. This view and the reverse (supinated) oblique view help identify fractures, especially involving the hook of the hamate and the pisiform.[5] The clenched fist, both PA and AP views, drive the capitate proximally as a wedge causing diastasis within the scapholunate joint, highlighting ligamentous instability (Table 51-2). Although scapholunate width may be exaggerated on the AP view, instability is suspected when either view shows a distance of 3 mm or greater.

Given the high incidence of occult fractures of the wrist, when radiographs are negative and pain persists, immobilization is

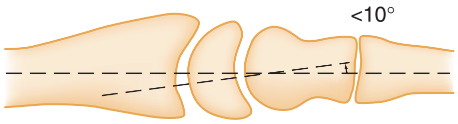

Figure 51-8. Normal relationship of carpal bones on a lateral radiographic view. Concavity of radius and lunate and convexity of capitate form three C-shaped areas *(stippled)* along a straight line that runs through the central axis of these bones.

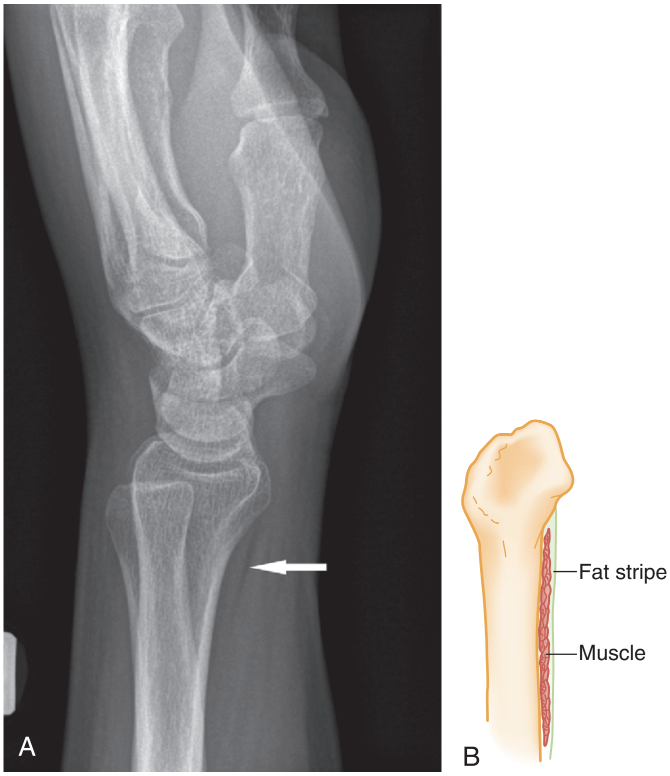

Figure 51-10. The pronator quadratus fat pad. Narrow fat stripe *(arrow)* located on the volar surface of the radius is seen on the lateral view of the wrist. Although not highly sensitive, volar displacements, anterior bowing, or complete obliteration of this line caused by hematoma in the setting of trauma is suggestive of wrist injury or fracture.

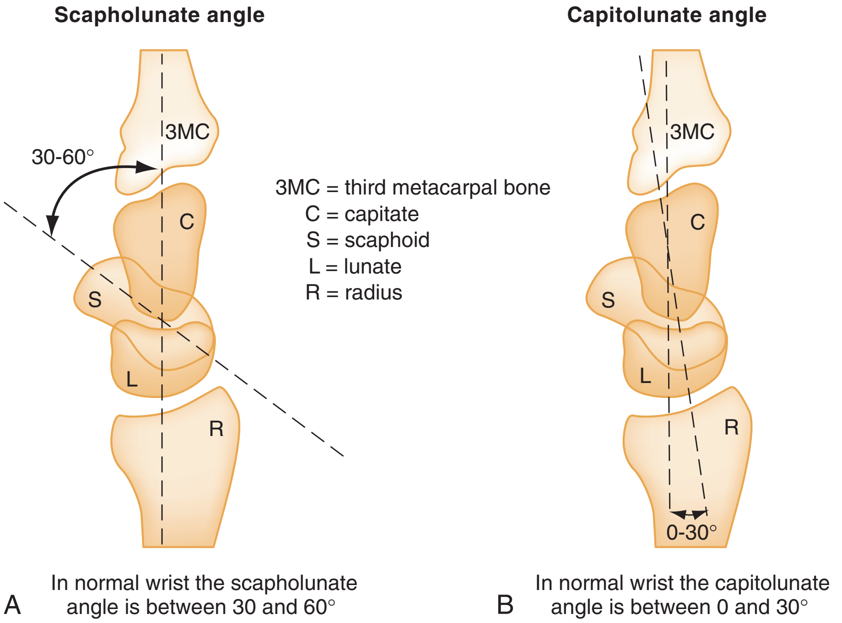

Figure 51-9. A, The normal scapholunate angle is formed by the intersection of the longitudinal axes of the scaphoid and lunate and normally measures 30 to 60 degrees. B, The normal capitolunate angle is formed by the intersection of the capitate and lunate central long axes and normally measures 0 to 30 degrees. (From Greenspan A: Orthopedic Radiology: A Practical Approach, 2nd ed. New York, Gower Medical Publishing, 1992.)

recommended. A thumb spica is usually added in the setting of suspected scaphoid and other carpal fractures, which is discussed in more detail below. In general, repeat physical examination, radiographs, or advanced imaging protocols are pursued urgently or after a period of observation. Although many studies regarding magnetic resonance imaging (MRI) and computed tomography (CT) protocols have already concluded that emergent advanced imaging is appropriate, more prospective and conclusive data are needed. The best data exists for scaphoid fractures and includes economic arguments. Although it is tempting to extend those conclusions to other carpus fractures, this would be premature, especially in view of the fact that these other injuries have less severe consequences and are more rare. In addition, highly sensitive emergent advanced imaging protocols are not readily available in many emergency departments (EDs), and as a result changes in management will likely be institution dependent.

Figure 51-11. Scaphoid waist fracture. A posteroanterior view of the wrist in ulnar deviation (scaphoid view) illustrates a nondisplaced fracture of the scaphoid waist *(arrow)*.

CARPAL INJURIES

Scaphoid Fractures

The scaphoid is the most commonly fractured bone of the carpus.[6] It accounts for approximately 70% of all carpal fractures. Typically seen in individuals 15 to 40 years of age, scaphoid fractures most commonly occur after a fall on the outstretched hand or as a sports-related injury.[7,8] Scaphoid fractures are rare in skeletally immature patients because the carpus is composed entirely of cartilage at birth and remains predominantly cartilaginous until late childhood and the adolescent years.[9] In pediatric patients, although the physis of the radius is likely to fail first, scaphoid fractures with and without this injury pattern have been observed.[9] In the elderly, a distal radius metaphysis fracture is more likely to occur than a scaphoid fracture.[8] Scaphoid fractures are classified by their anatomic location and may be divided into three groups: fractures of the tuberosity and distal pole, the waist, and the proximal pole. Of these three patterns, fractures through the waist of the scaphoid are the most common, accounting for approximately 70 to 80% (Fig. 51-11).[8]

Patients typically report dorsal radial wrist pain, distal to the radial styloid, with limited range of motion of the wrist and thumb. Classically, physical examination reveals tenderness on palpation of the scaphoid and swelling within the anatomic snuffbox. Increased sensitivities have been suggested for snuffbox tenderness with ulnar or radial deviation of the wrist with pronation. Pain also may be elicited with palpation of the scaphoid tubercle volarly, Watson's scaphoid shift test, axial compression of the first metacarpal, and pain on thumb–index finger pinch.[10] In an effort to not miss occult scaphoid fractures, the combination of clinical examination methods of tenderness in the anatomic snuffbox, on the scaphoid tubercle, and with first metacarpal compression has been suggested and may approach 100% sensitivity for disease.[10] When routine radiography is negative, a combination of these clinical examinations is used for maintaining a high sensitivity for identification of occult fracture, despite a low specificity (40-80%).[10-12]

Radiographic diagnosis of scaphoid fractures often is difficult, and special scaphoid views should be requested when a fracture is suspected based on clinical findings. A visible fracture lucency may be absent, and a more subtle change, such as obliteration or displacement of the scaphoid fat pad, may be the only clue to the presence of a fracture, although these signs are not reliably present.[13] Plain radiographs taken soon after injury fail to detect approximately 15% of scaphoid fractures.[14,15] In addition, because of the associated risk of nonunion, when diagnosis and immobilization are delayed, patients clinically suspected of having a scaphoid fracture are often treated with splint immobilization and repeat clinical evaluation, and radiographic imaging after 7 to 10 days.[16] Recent evidence has called into question the practice of immobilizing the wrist in all patients with suspected scaphoid injuries and has suggested that the use of more advanced imaging modalities is both accurate and cost-effective and should be performed earlier rather than later. The cost of time off from work, serial casting, repeat physician evaluation, and office visits easily exceed that of MRI, bone or CT scans for definitive diagnosis where these imaging modalities are readily available.[17,18] In addition to advanced imaging, clinical risk assessments and decision rules are being developed to help further risk stratify patients.[10]

MRI and CT imaging allows clinicians to diagnose the majority of radiographically occult scaphoid fractures and offer alternative diagnoses for wrist pain.[10,15] Macroradiography and ultrasound, including high-resolution sonography, have not approached the sensitivities and specificities observed with bone scintigraphy, MRI, and CT imaging. Despite extensive study, the optimal imaging modality and the sensitivity and timing of these studies in diagnosis of occult scaphoid fracture remain controversial.[10,19] As a result, these imaging modalities are not emergently performed on a routine basis.

www.ketabpezeshki.com 66485457-66963820

Figure 51-12. Short arm thumb spica splint. Common immobilization technique used for occult fractures of the scaphoid bone seen in volar view. Note the optimal 10 degrees of wrist flexion and radial deviation, which assists in scaphoid immobilization.

Figure 51-13. Avascular necrosis of scaphoid bone. A common complication of scaphoid fractures is avascular necrosis as a result of the distal to proximal osseous blood supply, displacement, or nonunion, resulting in chronic wrist pain and arthritis.

Historically, bone scans were used 72 to 96 hours after injury to detect scaphoid fractures. Although high sensitivities are quoted (97%), lower specificities, many false positives, decreased effectiveness in the elderly, and limited availability have tempered their use.[10,20,21] CT is excellent for detailed bone imaging, and it reveals the complications of fracture fragment displacement, malunion, and nonunion.[22] However, CT has not had the sensitivity required (93%) for diagnosing occult fractures in the emergent setting. Despite increased costs and more limited availability, MRI protocols have the advantage of allowing diagnosis of alternative soft tissue injuries and are being used to detect these radiographically occult fractures with sensitivity rates approaching 100%.[10,21,23-26] More prospective data on the optimal emergent and urgent diagnostic imaging modalities for occult scaphoid fractures are needed.

The definitive treatment for uncomplicated, nondisplaced scaphoid fractures is debated among orthopedic specialists, although trends toward screw fixation over cast immobilization are evident.[10] Emergency management typically involves immobilization in a thumb spica splint (Fig. 51-12). Immobilization with the wrist in 10 degrees of flexion with radial deviation is used to immobilize the fracture fragments of the scaphoid, and the majority of surgeons terminate the thumb spica at the interphalangeal joint line. Some specialists prefer a long arm (above the elbow) cast or splint, which prevents pronation and supination for the first few weeks. In addition to flexion and extension, pronation and supination have been suggested to produce fracture displacement in the proximal carpal row. Eventual replacement with a short arm cast for the remainder of the immobilization period may be acceptable. The duration of immobilization varies relative to the location of the fracture, but 6 to 12 weeks is common. More proximal fractures commonly require longer durations to ensure adequate healing. Variability in healing time is related directly to the pattern of blood supply to the scaphoid, which flows from the distal to the proximal portion of the bone through the scaphoid tuberosity. This pattern of blood flow also accounts for the higher incidence of AVN and nonunion in the more proximal fractures (Fig. 51-13). AVN is seen in approximately 13 to 40% and nonunion in 5 to 12% of scaphoid fractures, with the risk of complications being greatest in fractures of the proximal pole.[27-29] Because of the increased risk of AVN or nonunion, scaphoid fractures, especially those that are unstable, are displaced more than 1 mm, are associated with other fractures, or have an increased scapholunate or capitolunate angle, require urgent orthopedic referral for consideration of operative treatment.

Lunate Fractures

Fractures of the lunate are relatively uncommon and represent approximately 1 to 4% of all carpal fractures.[6,8,30,31] This injury occurs more commonly in persons with a congenitally short ulna, perhaps as a result of a compromised support for the TFCC. The usual mechanism of injury involves a fall on the outstretched hand, causing extreme dorsiflexion, with transmittal of the resultant force from the capitate to the lunate. Patients have pain over the dorsum of the wrist, which is exacerbated by axial loading of the long finger metacarpal. On physical examination, tenderness may be elicited by palpation over the dorsum of the wrist in the depression felt just distal to Lister's tubercle.

Fractures of the lunate may be difficult to see on plain radiographs because of overlap of the distal radius, ulna, and other carpal bones. For this reason, and because of the risk of AVN in missed injuries, clinically suspected lunate fractures should be immobilized. Nondisplaced lunate fractures are treated with immobilization in a short arm splint with a thumb spica, and patients are given orthopedic referral in 7 to 10 days. Displaced fractures should be reduced, and urgent orthopedic referral is warranted. Complications include progression to carpal instability, nonunion, and AVN. Lunate and perilunate dislocations are discussed later in the section on carpal instability. Post-traumatic AVN is a sequela in 20% of fractures and is presumed to be the cause of Kienbock's disease. In well-established cases of Kienbock's disease, the lunate appears sclerotic and fragmented on radiographic examination, and ultimately the bone collapses with resultant proximal migration of the capitate (Fig. 51-14). These changes cause secondary osteoarthritis of the radiocarpal joint and chronic wrist pain. Treatment involves operative intervention, with correction of the articular abnormalities either by lengthening the ulna or by shortening the radius. In more advanced cases, excision and prosthetic replacement of the lunate or arthrodesis may be necessary.[32]

www.ketabpezeshki.com 66485457-66963820

Figure 51-14. Avascular necrosis of the lunate bone *(circle),* also known as *Kienbock's disease,* is formally of unknown cause; however, prevailing theories support fracture of the lunate bone or compromised circulation as the most likely cause of disease.

Figure 51-15. Triquetral avulsion fracture. A minimally displaced triquetral avulsion or dorsal chip fracture *(arrow)* is seen on this lateral radiograph of the wrist.

Triquetral Fractures

Triquetrum injuries, second only to the scaphoid in incidence, account for approximately 15% of carpal fractures.[8] They usually result either from a direct blow to the bone, causing a fracture of the body, or much more commonly from a fall on the outstretched hand. In the former scenario, triquetrum body fractures are commonly associated with perilunate and lunate dislocations, and therefore ligamentous injury should be considered. A fracture to the triquetral body is best seen on the AP radiograph, and urgent orthopedic referral is suggested. In the latter scenario, the mechanism of fracture is believed to be impact of the ulnar styloid or proximal hamate against the triquetrum, which results in a dorsal avulsion fracture.[31,33] Patients have localized tenderness over the dorsum of the wrist just distal to the ulnar styloid. On physical examination, swelling may be noted in this same area, and wrist motion is limited secondary to pain. The fracture is best seen on the standard lateral view of the wrist as a small dorsal avulsion fragment, although, a more oblique pronated view may be necessary for visualization (Fig. 51-15). Treatment is with immobilization in a short arm splint or ulnar gutter with more routine orthopedic referral (1-2 weeks). Definitive treatment in a short arm cast usually results in an uncomplicated course, with prompt fracture healing over 4 to 6 weeks.

Pisiform Fractures

The pisiform is unique in the carpus because it is the only sesamoid bone and lies within the FCU tendon, articulating on its dorsal surface with the triquetrum. Although pisiform fractures are extremely rare, occurring in less than 1% of all carpal fractures, given the important role of the pisiform in forming the lateral wall of Guyon's canal, ulnar arterial damage and neurapraxias may be associated. Fractures of the pisiform usually occur from a fall on the outstretched hand but also may be seen after direct blows to the hypothenar eminence. Commonly this occurs from repetitive trauma when the palm of the hand is used in a hammer-like manner. On clinical examination, there is tenderness over the ulnar aspect of the wrist just distal to the volar crease. Pain may be exacerbated with wrist flexion and ulnar deviation. Paresthesias in the distribution of the ulnar nerve and hand clumsiness from intrinsic muscle dysfunction can occur. Pisiform fractures are poorly seen on routine wrist radiographs and are therefore likely under-reported, so special views should be requested. A reverse (supinated) oblique and the carpal tunnel view allow for better visualization of these fractures (Fig. 51-16).[4]

Fractures of the pisiform generally carry an excellent prognosis and are treated conservatively with immobilization in a short arm splint or ulnar gutter with orthopedic referral in 1 to 2 weeks. Definitive treatment is with a short arm cast for 3 to 4 weeks. Most pisiform fractures with evidence of ulnar nerve compromise, will resolve on their own; however, urgent orthopedic referral for consideration of surgical decompression is indicated. Pisiform fractures that are complicated by nonunion and pain may also require excision.

Hamate Fractures

Hamate fractures are rare and account for approximately 2 to 6% of all carpal bone fractures.[8] The hook or hamulus is the most common site of fracture, although articular surfaces and body fractures are also seen. Fracture of the hook usually occurs from a fall on the outstretched hand or from a direct blow to the palm. Classically, hook of the hamate fractures occur from those participating in racquet or club sports (e.g., tennis, golf, baseball). The use of hammers and vibration equipment (e.g., jack hammers) is

www.ketabpezeshki.com 66485457-66963820

Figure 51-16. Pisiform fracture. Reverse supinated oblique radiograph of the wrist profiling the pisotriquetral joint demonstrates minimally displaced pisiform fracture *(arrow)* not typically seen on traditional posteroanterior, lateral, and oblique views.

Figure 51-17. Hamate fracture. Fracture of the articular surface of the hamate bone *(arrow)* is seen on this posteroanterior radiograph of the wrist.

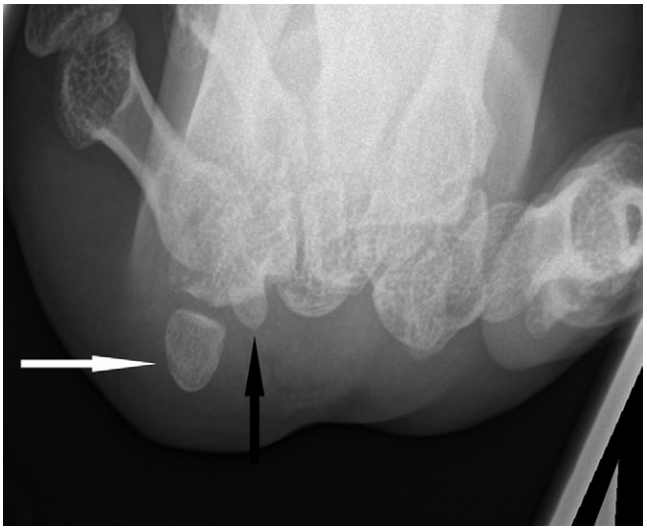

Figure 51-18. Carpal tunnel view of wrist. Pisiform *(white arrow)* and hook of hamate or hamulus *(black arrow)* are better visualized on carpal tunnel views of the wrist when clinical hypothenar palmar wrist pain is present and fracture is suspected.

also a common mechanism, which can predispose workers to hamate fractures, ulnar canal and hypothenar hammer syndrome.[34] Patients may have isolated pain over the hypothenar eminence, associated decreased grip strength, or compromised distal perfusion. Pain may be localized directly on palpation of the hamate, 1 cm distal and radial to the pisiform. Hamate body and articular surface fractures are usually caused by increased load to the ring and little finger metacarpals. These fracture patterns are best seen on PA views of the wrist (Fig. 51-17). Fractures of the hook are more easily seen on the reverse supinated oblique and carpal tunnel views (Fig. 51-18).[4] Because low sensitivities have been quoted for hook of the hamate fractures (40-70%), when radiographs are inconclusive and pathology is still suspected, CT scanning may be considered given its increased sensitivity, the complications of missed fracture, and changes in clinical management. The timing of CT scanning is debatable, and empirical treatment may be warranted. However, confirmed hook of hamate fractures should be splint immobilized with ulnar outrigger and thumb spica to limit traction from the transverse carpal ligament. Missed injury may result in complications, including delayed flexor tendon rupture affecting the little finger.[5,35] Fractures of the hook of the hamate may also be complicated by associated ulnar neurapraxia, which would warrant urgent orthopedic referral and is an indication for operative intervention with excision of the hook at the fracture site to restore function.[5] Vascular compromise or distal ischemia would warrant emergent orthopedic consultation.[36] Hamate body and articular fractures typically require closed or open reduction and internal fixation.

Trapezium Fractures

Fractures of the trapezium are also uncommon and represent approximately 3% of all carpal fractures.[8] There are two main types of fractures, those involving the body and the trapezial ridge. A direct blow to the adducted thumb causes fracture through the body of the trapezium, with transmittal of the force by the base of the thumb metacarpal. Avulsion fractures of the trapezial ridge occur with forceful radial deviation or rotation of the wrist. On examination, patients report pain with movement of the thumb and on direct palpation of the trapezium just distal to the scaphoid in the anatomic snuffbox. Although trapezium fractures may be seen on the AP view of the wrist, they are typically better visualized on oblique views (Fig. 51-19) and unfortunately are also commonly occult.[35] These injuries are treated with immobilization in a thumb spica splint, and patients are given orthopedic referral. Nondisplaced fractures are held in a cast for 6 weeks, whereas

www.ketabpezeshki.com 66485457-66963820

Figure 51-19. Trapezium fracture. An oblique view of the wrist shows an isolated, comminuted, intra-articular fracture of the trapezium body *(arrow).*

displacement or involvement of the carpometacarpal joint warrants urgent orthopedic referral for ORIF.

Capitate Fractures

The capitate lies in a central position in the distal carpal row, and because of this protected location, it is rarely fractured. When fracture does occur, the mechanism generally is a direct blow to the dorsum of the wrist. Fracture also may be seen in association with a perilunate dislocation after a fall on the outstretched dorsiflexed hand. Clinical examination reveals dorsal wrist pain and swelling, with localized tenderness on palpation of the capitate. Fractures usually are visible on the standard PA view of the wrist, although the lateral view may be helpful in determining the presence of rotation or displacement of the fracture fragment.

Nondisplaced isolated fractures of the capitate may be managed with immobilization in a short arm splint with thumb spica, with the patient given orthopedic referral. Urgent orthopedic referral is indicated for fractures with displacement, and emergency consultation for associated carpal dislocation. Complications of nonunion and AVN of the proximal fragment are rare but do occur because the capitate receives its blood supply through its distal half.

Trapezoid Fractures

Trapezoid fractures are rare, most commonly seen in association with other carpal injuries, and account for only approximately 1% of all carpal fractures.[5] The typical mechanism of injury is a direct blow down the long axis of the index metacarpal, which may result in isolated fracture to the trapezoid or cause a dorsal fracture-dislocation. On clinical examination, pain and tenderness are localized over the dorsum of the wrist at the base of the second metacarpal. The fracture may be visible on routine PA views of

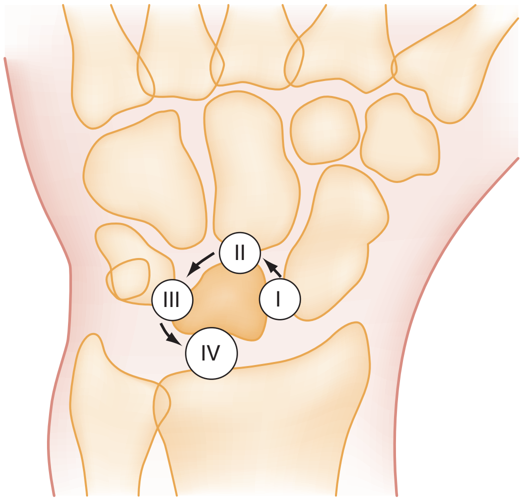

Figure 51-20. Sequential stages of carpal dislocation. Each of four stages represents a sequential intercarpal ligament injury proceeding around the lunate. (From Greenspan A: Orthopedic Radiology: A Practical Approach, 2nd ed. New York, Gower Medical Publishing, 1992.)

the wrist; however, oblique views may be superior for visualization of the injury. Nondisplaced trapezoid fractures should be immobilized with a short arm splint and thumb spica, and patients are given an orthopedic referral in 1 to 2 weeks. However, displaced fractures warrant urgent orthopedic referral for reduction and fixation.

Carpal Instability

Mayfield and associates described a progressive pattern of carpal ligamentous injury caused by wrist hyperextension, ulnar deviation, and intercarpal supination.[37] Their studies of the pathomechanics of these injuries led to the classification of carpal instability into four distinct stages. Each stage represents a sequential intercarpal injury beginning with scapholunate joint disruption and proceeding around the lunate, creating progressive carpal instability (Fig. 51-20). Each stage also may be associated with specific bony fractures, which, if present, should alert the physician to the possibility of an occult perilunate ligamentous injury. These associated injury patterns include fractures of the radial styloid, scaphoid, capitate, and triquetrum.

A *stage I injury,* or scapholunate dissociation, results in a characteristic widening of the scapholunate joint on the PA view, which has been called the "Terry Thomas sign," after the British comedian with a gap between his front teeth.[38] This radiographic sign has been updated to reference more current celebrity figures and is also referred to as the "Madonna sign" or the "David Letterman sign." This injury pattern may be associated with a rotary subluxation of the scaphoid. Radiographically the scaphoid is seen end on, with the cortex of the distal pole appearing as a ring shadow, referred to as the "signet ring sign" (Fig. 51-21). Scapholunate dissociation may not be demonstrated on routine radiographs, so when clinical examination reveals tenderness to palpation, suggesting ligamentous injury, additional stress views could be considered. Radiographs taken with a clenched fist and with ulnar deviation (the clenched-fist AP view) accentuate widening of the scapholunate joint and are suggestive of disease when a gap greater than 3 mm is observed.

A stage *II injury,* or perilunate dislocation, is seen best on the lateral view of the wrist. Although the lunate remains articulated to the distal radius, the capitate is dorsally dislocated. The PA view shows overlap of the distal and proximal carpal rows and also may

www.ketabpezeshki.com 66485457-66963820

show an associated scaphoid, radial styloid, or capitate fracture (Fig. 51-22).[39]

A *stage III injury* appears identical to a stage II injury but includes a dislocation of the triquetrum that is seen best on the PA view, with overlap of the triquetrum on the lunate or hamate. This injury may be associated with a volar triquetral fracture.

A *stage IV injury,* or lunate dislocation, results in a characteristic triangular appearance of the lunate on the PA view that is caused by the rotation of the lunate in a volar direction. This triangular appearance is known as the "piece of pie sign." This rotation also is visible on the lateral view of the wrist, in which the lunate looks like a cup tipped forward and spilling its contents, referred to as the "spilled teacup sign." On the lateral view, the capitate is seen to lie posterior to the lunate and often has migrated proximally to contact the distal radius (Fig. 51-23).

Patients with these carpal dislocation injuries typically have a history of a fall on the outstretched hand. They complain of pain and swelling over the dorsum of the wrist, with limited range of motion. On physical examination, tenderness to palpation is noted over the dorsum of the wrist, particularly in the region of the scapholunate ligament. Scapholunate instability may be clinically elicited by a provocative maneuver, such as Watson's scaphoid shift test, which will increase pain and produce a clunk or snap.[40] This test is performed by placing upward pressure on the scaphoid tuberosity while the hand is in ulnar deviation. In scapholunate instability, this action will cause the scaphoid to ride out of the radial fossa over the dorsal rim, and as the hand is moved back radially, a painful snap is produced.[41,42] In the setting of acute trauma, unfortunately, this test frequently proves to be too painful to perform. With perilunate and lunate dislocations, visible deformity of the wrist also is apparent, and two-point sensation in the

Figure 51-21. Scapholunate dissociation with scaphoid subluxation. Posteroanterior view of the wrist shows characteristic widening of the scapholunate joint *(black arrow),* known as the "Terry Thomas sign," and a ring shadow over the scaphoid *(white arrow)* secondary to subluxation and known as the *signet ring sign.*

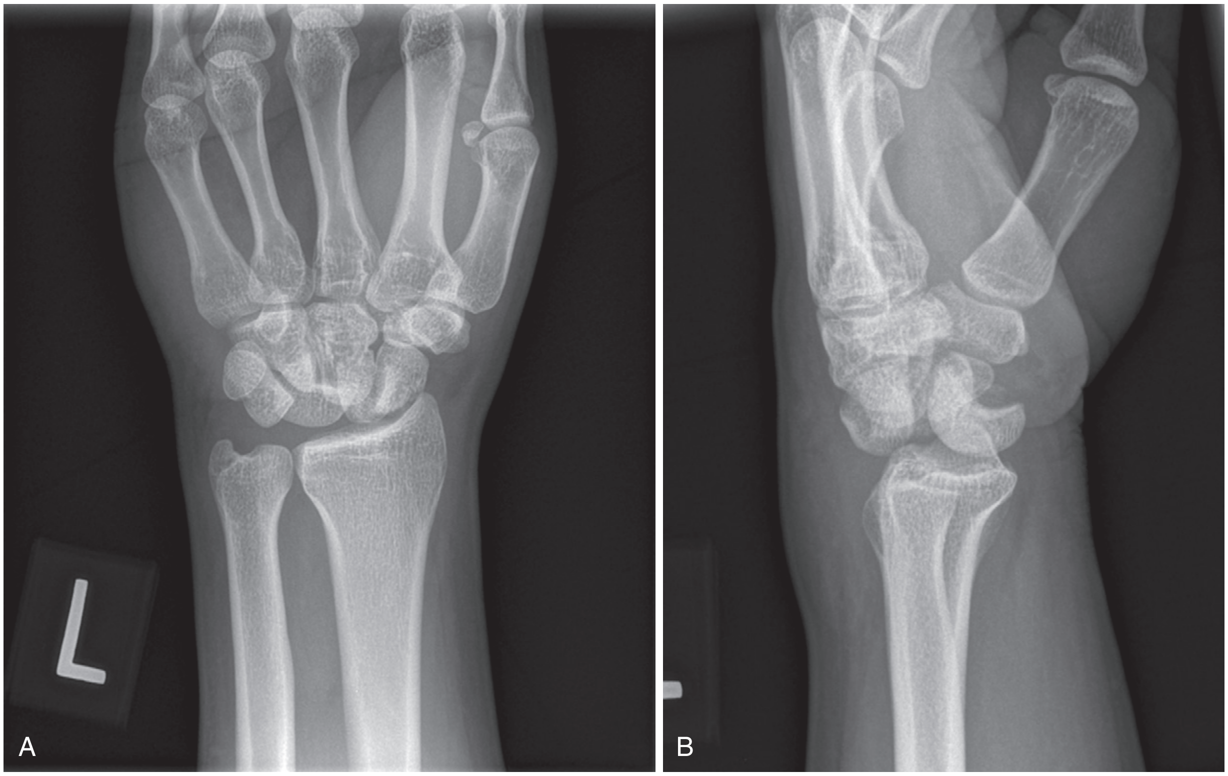

Figure 51-22. Perilunate dislocation. **A,** This posteroanterior view of the wrist shows an abnormal appearing lunate bone, obvious disruption of the normal carpal arcs, and the commonly associated, and in this instance, displaced scaphoid fracture. **B,** Lateral view shows a dislocated and dorsally displaced capitate bone in relation to the lunate. Of note, the lunate maintains its articular connection and alignment with the radius, suggesting perilunate dislocation.

www.ketabpezeshki.com 66485457-66963820

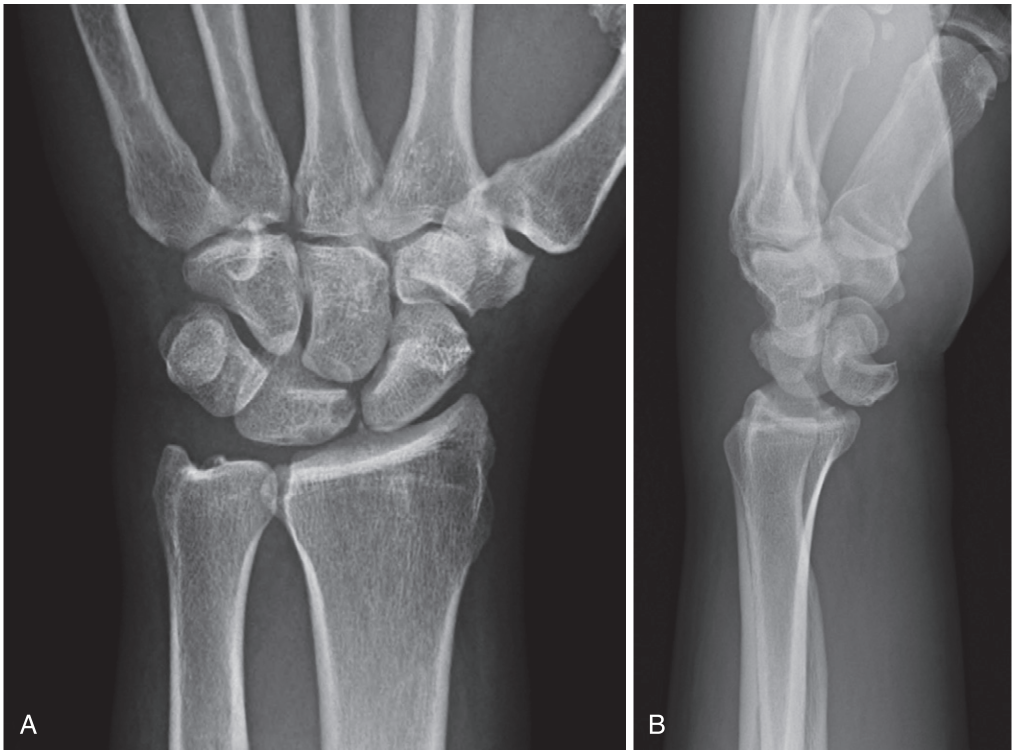

Figure 51-23. Lunate dislocation. **A**, This posteroanterior view shows the characteristic triangular shape of the lunate bone during dislocation. **B**, Volar displacement of the lunate resembles a spilled teacup on the lateral view. Note the disrupted articulation between the lunate and distal radius and realignment of radius, capitate, and metacarpals, suggesting lunate dislocation.

median nerve distribution often is diminished. Complications of carpal dislocation injuries include median nerve injury and chronic carpal instability with resultant degenerative arthritis.

MRI has been shown to have relatively low sensitivity (63%) and specificity (86%) for the diagnosis of scapholunate injury.[43,44] Arthroscopy remains the "gold standard" modality for identifying and grading scapholunate injuries. It allows superior detection of internal derangement of wrist ligaments and a more accurate visualization of the articular surfaces.[41]

Carpal dislocation injuries need emergent orthopedic consultation in the ED for reduction and stabilization. Either arthroscopically guided reduction with pinning or ligament repair can be considered in management of these acute injuries.

Midcarpal and Intercalated Segment Instability

Clinically significant abnormal wrist kinematics may be seen in the ED as midcarpal instability (MCI), including dorsal intercalated segment instability (DISI) and volar intercalated segment instability (VISI).[45,46] The midcarpal joint lies between the proximal and distal carpal rows. The proximal row of carpus bones is known as the *intercalated segment* and moves passively with no direct muscular insertions. Clinically, patients have chronic pain, weakness, and limited range of motion and may report wrist clicking. On physical examination, point tenderness may be elicited over the area of primary injury, usually the scapholunate or lunotriquetral joints. Gross deformity of the wrist, resulting from subluxation, also may be apparent on comparison with the unaffected "normal" wrist.

When ligamentous injury is present, MCI, DISI, and VISI patterns of carpal instability may be recognized radiographically by specific deformities on the lateral view of the wrist (Fig. 51-24). Although the radiographic angles appear complex, a simple approach to diagnose DISI and VISI carpal instability is to locate the lunate, which is one of the easiest carpal bones to visualize on the lateral radiograph. If the lunate is tilted dorsally with respect to the radius, a DISI pattern is suspected; conversely, if the lunate is tilted volarly, a VISI pattern is suspected. A DISI pattern of instability is identified by an increase in both the scapholunate and capitolunate angles, whereas the VISI pattern has a decrease in the scapholunate angle and an increase in the capitolunate angle. DISI is the most common pattern of carpal instability and may occur after scapholunate dissociation or with scaphoid fractures with or without associated perilunate dislocation. VISI occurs after lunotriquetral or triquetrohamate joint disruption.[47] Either pattern may be seen in association with radiocarpal joint malalignment, as is seen in lunate collapse with Kienbock's disease, rheumatoid arthritis, or congenital carpal ligamentous laxity.[42,45] Patients should be splinted and referred to an orthopedic surgeon for definitive stress view radiographs, videofluoroscopy, and advanced CT and MRI imaging for treatment of these injuries. The optimal treatments, which may be surgical reduction, stabilization, and ligamentous repair, are debated in the orthopedic literature.[48]

Radiocarpal Instability

Although radiocarpal dislocations and fracture-dislocations are considered extremely rare, representing only 0.2% of all dislocations, some consider this diagnosis to be under-reported.[49,50] High-energy trauma is the mechanism of injury; patients usually have many additional injuries and are commonly involved in polytrauma scenarios. Dislocations may be volar or dorsal, and ulnar translation of the carpal bones is much more common than radial. Emergent reduction of these injuries is paramount because of the extensive soft tissue damage and commonly associated distal

neurovascular compromise.[51] Reduction is, however, commonly difficult to maintain in these complex and unstable injuries, which usually require ORIF. Emergent orthopedic consultation in the ED is indicated.

DISTAL RADIUS AND ULNA INJURIES

Distal radius and ulna fractures remain some of the most common injuries seen in EDs worldwide. Women older than 50 years, who are most vulnerable, can carry a 15% lifetime risk of this injury pattern. Occurring, in general, from a fall on the outstretched hand in older patients and from high-energy trauma in younger patients, these injuries are commonly closed, may have intra-articular involvement and displacement, and frequently require closed reduction, splinting, and outpatient orthopedic referral. Numerous classification patterns have been devised, and the most commonly encountered fractures are discussed in the following sections.[52]

Colles' Fracture

Colles' fracture, first described in 1814, is the most common wrist fracture seen in adults.[53] It is a transverse fracture of the distal radial metaphysis, which is dorsally displaced and angulated, causing the classic "dinner fork" deformity seen on physical examination. The fracture usually is located within 2 cm of the radial articular surface and may be associated with comminution and intra-articular extension into the radiocarpal or radioulnar joints. There is commonly an associated fracture of the ulnar styloid in 60 to 70% of cases, which may suggest concomitant injury to the TFCC.[54] A neurovascular examination should be performed to exclude any neurapraxia or vascular compromise caused by the deformity or fracture fragments.

The PA and lateral views of the wrist show the fracture through the radial metaphysis. The PA view may show extension of the fracture into the radioulnar or radiocarpal joints and the amount of intra-articular step-off and radial shortening present. The degree of dorsal displacement and angulation is best seen on the lateral view, with loss of the normal volar tilt of the distal radial articular surface (Fig. 51-25).

Many Colles' fractures require early anatomic reduction with restoration of radial length and correction of the dorsal angulation either to a neutral position or ideally restoring the normal volar tilt.[54] This procedure is often performed by emergency physicians. Closed reduction may be assisted by intravenous analgesia, local or regional anesthesia, or procedural sedation and is followed by sugar-tong splint immobilization. This treatment may be definitive and, if successful, allows for outpatient orthopedic referral in the majority of cases. Methods of local and regional anesthesia for distal radial fracture reduction include the classic hematoma block; intravenous regional anesthesia, known as the *Bier block*, which is not routinely taught to emergency physicians today; and regional nerve blocks, including radial, median, ulnar, or brachial plexus approaches.[54] The hematoma block remains an effective method of anesthesia and is performed by placing a 22-gauge needle in the dorsum of the distal radius, withdrawing until a fracture hematoma is encountered, then instilling 5 to 10 mL of 2% lidocaine (Fig. 51-26). Use of finger traps also is an effective means of obtaining the reduction to allow positioning for splinting (Fig. 51-27). The more comminuted and displaced the fracture, the higher the likelihood that operative reduction will be necessary. Common emergent indications for Colles fracture reductions include any neurovascular compromise, significant soft tissue tension, or tenting of the skin. More debatable indications for emergent or urgent reduction include a loss of volar tilt with significant dorsal angulation (>10-20 degrees), radial shortening or a positive ulnar variance greater than 2 mm. An intra-articular

Figure 51-26. Hematoma block. Sterile preparation of the fracture area is performed, and local anesthetic is then introduced to the hematoma that surrounds the fracture site to assist with pain control during reduction.

step-off less than 1 to 2 mm and radial inclination less than 15 degrees are also considered optimal in younger patients but difficult to affect with closed reduction.[54,55] Loss of reduction will occur in many of these patients before follow-up, especially the elderly, in whom the long-term benefits of anatomic restoration are questioned.[56] Emergent orthopedic consultation should be considered if initial attempts at closed reduction are unsuccessful and there is associated neurovascular compromise, clinical compartment syndrome, or if the fracture is open.

Complications of Colles' fracture are seen most often in elderly patients and those with inadequate fracture reduction.[54-57] Although radial and ulnar nerves may be compromised, median nerve injury is most common and may occur acutely from contusion, traction from displacement, transection from fracture fragments, nerve compression after closed reduction, overlying cast pressure, or secondary to acute carpal tunnel syndrome (CTS; discussed later).[57] Overlying skin and soft tissues are at risk, and tendon injury has been reported. For this reason, it is important to evaluate neurologic function before and after fracture reduction.

Smith's Fracture

Smith's fracture is a transverse fracture of the metaphysis of the distal radius, with associated volar displacement and angulation. In some cases, the fracture may extend into the radiocarpal joint. On physical examination it is known as the *garden spade deformity* but because displacement is opposite to that seen in Colles' fracture, Smith's fracture often is called a *reverse Colles' fracture.* The typical mechanism of injury involves a direct blow to the dorsum of the wrist or a fall onto the dorsum of the hand resulting in extreme palmar flexion. The fracture also may be seen after a fall backward on an outstretched hand with the forearm in supination. The patient has a swollen, painful wrist, which is deformed, with fullness visible on the volar aspect. The fracture is visible on PA and lateral radiographs of the wrist, but the lateral view best shows the degree of volar displacement and angulation (Fig. 51-28).

Treatment of this fracture involves closed reduction and immobilization in a sugar-tong splint as discussed earlier. Unlike Colles' fracture, however, Smith's fracture is much more likely to be unstable and to require operative repair and splint reduction, and has an increased tendency to cause neurovascular compromise, specifically median nerve compression. Urgent orthopedic referral or emergent consultation is indicated based on the severity of angulation, neurovascular compromise, or associated soft tissue complications. Similarly, prognosis is most favorable in patients with successful reduction and restoration of the normal radial length and volar tilt.[54,58]

Barton's Fracture

Barton's fracture is an oblique intra-articular fracture of the rim of the distal radius, with displacement and dislocation of the

www.ketabpezeshki.com 66485457-66963820

carpus along with the fracture fragment. The fracture may involve the dorsal rim of the radius with dorsal carpal subluxation (classic Barton's fracture), or it may involve the volar rim with volar carpal subluxation (volar Barton's fracture). These fractures are rare and account for only 1% of all distal radius fractures.[59] The volar-anterior margin fracture is seen more often than the dorsal-posterior margin fracture.

The mechanism of injury for these fractures is a high-velocity impact across the articular surface of the radiocarpal joint, with the wrist in either volar flexion (causing a volar rim fracture) or dorsiflexion (causing a dorsal rim fracture). Volar and dorsal rim fractures are easily visible on PA and lateral wrist radiographs; however, the lateral view best shows the degree of articular surface involvement and the amount of associated fracture displacement (Fig. 51-29).

Treatment of these fractures requires emergent orthopedic consultation for reduction and stabilization. Closed reduction occasionally may be successful. Most authorities now advocate early operative management with either closed reduction performed under fluoroscopy, followed by percutaneous pinning or ORIF to accurately restore the articular surface of the radius and stabilize the carpus.[59] Complications include post-traumatic arthritis of the radiocarpal joint and delayed carpal instability. Both complications are seen more commonly when reduction fails to achieve or maintain anatomic realignment of the radiocarpal joint surface.

Hutchinson's Fracture

Hutchinson's fracture, or chauffeur's fracture, is an intra-articular fracture of the radial styloid. The mechanism of injury is usually a direct blow or fall resulting in trauma to the radial side of the wrist. The term *chauffeur's fracture* originated in the era of hand-cranked automobiles, when this injury occurred because of direct

Figure 51-27. Finger traps. Distal radius reduction method typically involves traction followed by manipulation facilitated by the finger traps. Ten pounds of weight are hung from the elbow at 90 degrees of flexion for approximately 10 minutes before the reduction attempt.

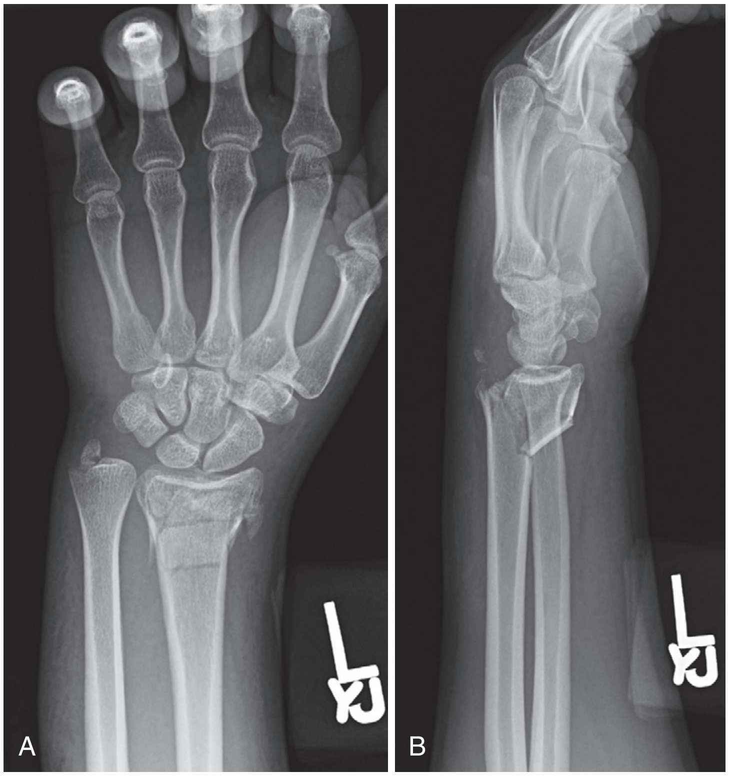

Figure 51-28. Smith's fracture. **A,** Posteroanterior view shows a metaphyseal fracture of the radius with shortening and associated ulnar styloid base fracture. **B,** Lateral view shows volar displacement of the distal fracture fragment along with the carpus.

trauma to the radial side of the wrist from the recoil of the motor crank. The fracture is seen best on the PA view of the wrist as a transverse fracture of the radial metaphysis with extension through the radial styloid into the radiocarpal joint.

Nondisplaced fractures may be immobilized in a sugar-tong splint, with the patient given urgent orthopedic referral; definitive treatment is in a short arm cast. However, displaced fractures, which are frequently associated with scapholunate ligament disruption, require open or closed reduction and fixation (Fig. 51-30). Because the radial styloid is the primary site of attachment for many of the ligaments of the wrist, accurate fracture reduction and union are crucial for wrist function.[60] Post-traumatic arthritis is a common complication of radial styloid fractures and more common with displacement and scapholunate ligament disruption.

Distal Radioulnar Joint Disruption

Acute dislocation of the DRUJ can occur as an isolated injury, which is rare, or in association with a fracture to the distal radius (Colles' fracture), radial diaphysis (Galeazzi's fracture), or radial head (Essex-Lopresti injury).[61,62] Diagnosis often is difficult because when the injury occurs in isolation or is not suspected, plain radiographs commonly are reported as normal in appearance. Certain characteristic findings on clinical examination may constitute the only clue to the presence of this injury.

The typical mechanism of injury is a fall on the outstretched hand with either hyperpronation, resulting in dorsal dislocation, or hypersupination, causing volar dislocation of the ulna. Dorsal ulna dislocations are more common than volar dislocations.[6,62] Another mechanism known to cause DRUJ dislocation is the catching of the hand in rotating machinery, resulting in the same forcible hyperpronation or supination. This forcible rotation of

Figure 51-30. Hutchinson's fracture. Posteroanterior radiographic view shows intra-articular fracture of the radial styloid with displacement and scapholunate dissociation, a common complication of untreated Hutchinson's fracture.

the wrist causes disruption of the TFCC, the major stabilizer of the DRUJ, and may result in an associated avulsion fracture of the ulnar styloid.

Patients with this injury have a history of sudden onset of pain with a "snapping" sensation in the wrist, swelling, and limited range of motion. On examination, tenderness is present over the ulnar aspect of the wrist, with palpable crepitus on supination and pronation. With a dorsal dislocation of the ulna, the ulnar styloid appears more prominent than on the unaffected side, and significant pain and limitation of movement are noted on supination of the wrist. With a volar dislocation of the ulna, there is loss of the normal ulnar styloid prominence, with pain and limitation of movement on pronation. These characteristic clinical findings should alert the physician to the possibility of DRUJ disruption and prompt the appropriate investigations to confirm the presence or absence of this injury.[63]

Well-positioned lateral radiographs of the wrist may show the presence of a DRUJ dislocation with more than 20 degrees of dorsal angulation or volar displacement, but pain and inability of the patient to rotate the wrist fully may cause a false-negative result because a true lateral view cannot be obtained.[64] Fractures of the ulnar styloid base should increase suspicion regarding a DRUJ disruption. It also is important to assess for radial head fractures because this injury is commonly associated with DRUJ disruption and interosseous membrane rupture (Essex-Lopresti injury).[65] A DRUJ dislocation is seen on the PA view of the wrist showing significant overlap or widening of the distal radius and ulna (Fig. 51-31). If there is significant clinical suspicion of injury and the radiographic appearance is normal, a CT scan may assist in the diagnosis.[66,67]

Treatment of these injuries commonly requires orthopedic consultation for reduction and stabilization. Closed reduction with the forearm in supination followed by application of a long arm cast often is successful. Alternatively, open reduction frequently is necessary with volar dislocations because the ulnar head often is locked on the distal radius. Operative reduction also is necessary in dorsal dislocations to repair the associated injury to

www.ketabpezeshki.com 66485457-66963820

the TFCC. Immobilization in a long arm cast usually is maintained for 6 weeks.

Pediatric Fractures of the Distal Radius

Fractures of the distal radius in children may be divided into two types: fractures involving the distal radial metaphysis and fractures involving the growth plate. They usually occur as a result of a fall on an outstretched hand with the wrist forcibly dorsiflexed. Fractures of the radial metaphysis are of three types: torus fractures, greenstick fractures, and complete fractures.

The periosteum of growing immature pediatric bone is strong but more pliable than completely matured adult bone, often leading to bowing injuries of the radial metaphysis rather than the typical fracture patterns seen in adults. The torus fracture is the most common of these radial metaphyseal fractures and results in a buckling of the radial cortex, which occurs without significant displacement (Fig. 51-32).[68] These fractures are treated with immobilization in a short arm splint with orthopedic referral and follow-up evaluation.[69,70] Healing usually occurs over 2 to 3 weeks, and complications are rarely seen.[71] Mild angulation remodels well in children, allowing for acceptance of the fracture "as it lies" in many cases. As a result, studies now debate the need for definitive casting and orthopedic evaluation for simple nondisplaced torus fractures of the distal radius.

Greenstick fractures also are incomplete metaphyseal fractures, with disruption of the cortex on one side and angulation or bowing on the opposite side (Fig. 51-33). Commonly, these fractures are displaced and require reduction if angulated more than 10 degrees. Angulations of less than 10 degrees usually remodel. Short arm splint immobilization is recommended, with close orthopedic follow-up to ensure maintenance of reduction.

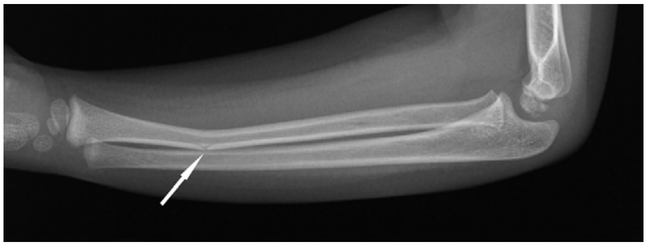

Figure 51-33. Greenstick fracture. Angulation and bowing of the distal radius with a greenstick-type pediatric fracture *(arrow)* is pictured in this lateral view of the forearm.

Complete fractures of the radial metaphysis involve disruption of both cortices of bone and usually result in significant displacement and angulation. These injuries also may be associated with a fracture of the distal ulna. Closed reduction may be successful; however, if the fracture is unstable or open, if there is neurovascular compromise, or if compartment syndrome is a concern (discussed later), emergent orthopedic consultation is indicated.[72]

In 1963, Salter and Harris classified growth plate injuries in children.[73] A discussion and descriptive table of the Salter-Harris I to V classification system may be found in Chapter 176. Growth plate, or physeal fractures, of the distal radius are usually Salter-Harris type I or II. Although these injuries result in disruption of the growth plate, they rarely result in growth disturbance.[68,73] Type I injuries cause pain and palpable tenderness over the distal radial physis. There may be no radiographic abnormality, or subtle volar displacement of the pronator quadratus fat pad may be observed. Type II injuries involve a fracture through the radial metaphysis and the physis and are visible on routine wrist radiographs as a triangular metaphyseal fragment on the dorsal surface of the radius. These fractures may be complicated by displacement of the radial epiphysis or by an associated fracture of the distal ulna (Fig. 51-34). These injuries may be treated with short arm splint immobilization and given orthopedic follow-up evaluation within 1 week of the injury. Immobilization or closed reduction may be sufficient; however, operative fixation may be necessary if adequate alignment cannot be achieved or maintained with casting.

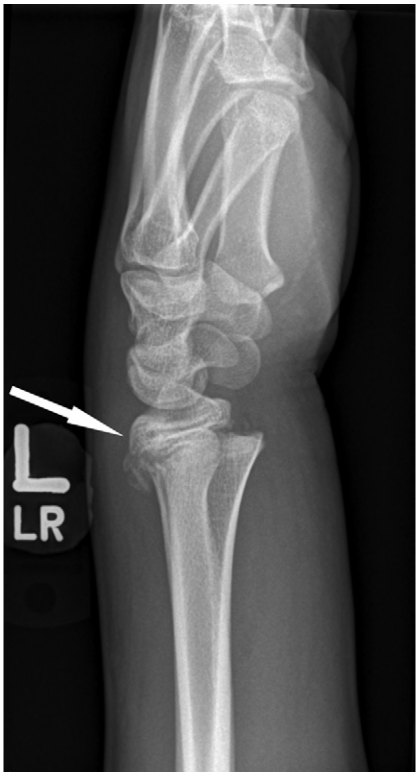

Figure 51-34. Salter-Harris type II distal radius fracture. A Salter-Harris type II distal radial fracture with triangular metaphyseal fragment and dorsal displacement *(arrow)* is pictured in this lateral view of the pediatric wrist.

SOFT TISSUE INJURIES OF THE WRIST

Carpal Tunnel Syndrome

CTS is the most common entrapment neuropathy that occurs at the wrist as a result of compression of the median nerve. CTS has an overall lifetime incidence ranging from 3 to 6%, with a female preponderance.[74,75] The transverse carpal ligament and the volar surfaces of the carpal bones form the carpal tunnel. It is a rigid compartment that contains nine flexor tendons (the flexor pollicis longus tendon, four flexor digitorum superficialis tendons, and four flexor digitorum profundus tendons) and the median nerve. Any process, local or systemic, that results in an increase in pressure within this compartment may produce CTS.

The most common causes of CTS are distal radius fractures and repetitive strain. CTS also can be associated with numerous systemic conditions, such as rheumatoid arthritis, hypothyroidism, diabetes mellitus, renal failure, congestive heart failure, acromegaly, and collagen vascular diseases.[76] Each of these systemic diseases is thought to produce an increase in pressure within the carpal tunnel from thickening of the flexor synovia or transverse carpal ligament. Hormonal changes associated with pregnancy and menopause also are known to cause CTS, probably from retention of fluid in the soft tissues about the wrist.[75,77]

Figure 51-35. Phalen's test.

The classic symptoms include a gradual onset of numbness, paresthesia, and pain in the thumb, index, and long fingers. These symptoms often are bilateral and are worse during the night and after strenuous activities. Typically, patients report numbness and paresthesias on awakening that lessen when the hands are shaken or held in a dependent position. The paresthesias are in the classic median nerve distribution and can be seen in a Katz diagram (see Table 51-1).

Examination of the neck and chest is important to detect cervical radiculopathy or thoracic outlet syndrome, which can mimic CTS. The most common provocative test is the wrist flexion or Phalen's test (sensitivity of 76% and specificity of 80%) (Fig. 51-35).[78] This test is performed by asking the patient to flex the wrists fully for 60 seconds while holding the forearms in a vertical

www.ketabpezeshki.com 66485457-66963820

position. The test result is positive if paresthesia or numbness develops in the median nerve distribution.

Another test for CTS is Tinel's sign, which demonstrates pain or paresthesias in the median nerve distribution elicited by light tapping or percussion over the median nerve at the wrist. Analysis of the literature suggests, however, that Tinel's sign (sensitivity of 42 to 85%; specificity of 54 to 98%) is not as powerful as Phalen's test in detecting median nerve compression.[79] An additional test, Durkan's or the median nerve compression test, which consists of application of pressure directly over the median nerve at the carpal tunnel, has a sensitivity of 87% and specificity of 90%.[80]

Because none of these physical tests is completely reliable in making the diagnosis of CTS, nerve conduction studies have been used to confirm the diagnosis, with reports of 85 to 90% sensitivity.[79] MRI and high-resolution ultrasound studies occasionally are used for confirmation, but the diagnosis of CTS is primarily clinical.[80]

Conservative (nonoperative) treatment for CTS yields variable results. Specific measures include splinting the wrist in a neutral position and administering cortisone injections in the carpal tunnel. Splinting initially may be prescribed full time and then reduced to splinting at night only. Kaplan identified five important factors that lessen the likelihood of successful nonoperative treatment: (1) age older than 50 years, (2) duration longer than 10 months, (3) constant paresthesias, (4) stenosing flexor tenosynovitis, and (5) positive Phalen's test result at less than 30 seconds. Two thirds of patients in his series were cured by medical treatment when none of these factors were present. However, 59.6% with one factor, 83.3% with two factors, and 93.2% with three factors did not improve. No patient with four or five factors was cured by medical management.[81] Nonsteroidal anti-inflammatory drugs (NSAIDs) have proved to be of little benefit. Surgical release of the flexor retinaculum to unroof the carpal tunnel is indicated when medical management fails.[82]

Acute carpal tunnel syndrome (ACTS), which occurs over hours rather than weeks, months, or years, is much less common than the chronic, gradually progressive presentations of CTS requiring symptomatic relief, appropriate referral, and patient education. ACTS is more often directly related to fractures, fracture-dislocations, hemorrhagic conditions, infections, vascular disorders, and edema involving the wrist.[83] Although the carpal tunnel is open at both ends, it has the physiologic properties of a closed compartment.[84] Distal radius fractures are likely the most common cause of ACTS; however, lunate and perilunate dislocations are associated, and even isolated carpal fractures and rupture of the extensor pollicis longus (EPL) tendon have been documented as rare causes. No reliable clinical method currently exists for differentiating acute median nerve compression in ACTS from concussive insult. In the absence of trauma, ACTS has occurred secondary to hemorrhagic, vascular, and bleeding disorders and anticoagulant use. When ACTS has been diagnosed, orthopedic consultation is recommended for immediate surgical decompression and release of the transverse carpal ligament. This may preserve nerve function and prevent post-traumatic complex regional pain syndromes.[83,85,86]

de Quervain's Disease and Intersection Syndrome

de Quervain's disease and intersection syndrome, like CTS, have been grouped into the overuse or repetitive strain injury pattern category, sometimes referred to as *work-related cumulative trauma* in the occupational medical literature. The APL and EPB, both within the first dorsal extensor compartment of the wrist, are the tendons affected in de Quervain's disease. Traditionally known as a stenosing tenosynovitis, tendonitis, or tendovaginitis of the wrist, de Quervain's disease involves enlarged tendons, which may reach five times their original size, creating a stenosing tendinopathy. Clinically, patients report pain on the radial side of the wrist, with ulnar deviation, thumb movements, weakened grip strength, or a combination of these symptoms. Onset is gradual and typically the result of increased use. There are no large epidemiologic studies, but de Quervain's disease is thought to be common, affecting women six times more frequently than men, and typically at an age older than 40 years. Radiographs are useful in ruling out bony pathology, but the diagnosis may be made with physical examination only.

Originally described in 1930, Finkelstein's test has long been considered to be a pathognomonic sign of de Quervain's disease. The test is named after the Swiss surgeon Fritz Finkelstein, who said, "On grasping the patient's thumb and quickly abducting the hand ulnarward, the pain over the styloid tip is excruciating. This is probably the most pathognomonic objective sign."[87]

There are surprisingly few prospective randomized controlled studies with good methodological quality regarding treatment of de Quervain's disease. Conservative interventions of rest, splinting, NSAIDs, and corticosteroid injections of the dorsal extensor compartment of the wrist are the first-line treatments for mild to moderate disease. Wrist splints with thumb spicas effectively immobilize the APL and EPB, but pain may return when inciting activity is resumed. Use of corticosteroid preparations with local anesthetic has been reported to be successful. Patients with refractory or severe cases of de Quervain's disease that interfere with the activities of daily living undergo surgical release of the first dorsal extensor compartment of the wrist with decompression of the APL and EPB tendons.[88]

Intersection syndrome is another overuse tendinopathy that clinically manifests with pain on the radial side of the wrist approximately 4 to 8 cm proximal to the site of de Quervain's disease. The condition is also known as *peritendinitis crepitans* or *crossover* or *oarsman's syndrome.* The mechanism of injury is secondary to rowing, weightlifting, or a repetitively resisted pulling action. Pathophysiologically, intersection syndrome occurs secondary to inflammation where the muscle bellies of the APL and EPB cross over the muscle bellies of the extensor carpi radialis longus and brevis proximal to the retinaculum. Physical examination findings include significant pain, soft tissue swelling, and crepitus with movement in more severe cases. Ultrasound findings may include thickened tendons or effusion, and radiographs are negative. The treatment for this disease is immobilization with a wrist splint and anti-inflammatory medication. Although surgical treatments have been described, this syndrome is typically self-limited.[89]

FOREARM

PERSPECTIVE

Forearm injuries are one of the common encounters in the ED. In children, forearm fractures account for almost half of the all pediatric fractures.[90] Mechanisms of injury include falls on outstretched hands, direct blows to the area, or involvement in motor vehicle collisions. Evaluation of forearm injuries requires understanding of the interdependent biomechanical relationship between the radius and ulna. These two bones articulate at both the proximal and distal ends, which allows the radius to rotate around the ulna to provide pronation and supination. As the fracture of either radius or ulna can result in dislocation at the wrist or elbow, emergency physicians should be vigilant when treating forearm fractures. Early diagnosis and prompt treatment of these injuries are critical if full function of the forearm is to be retained.

www.ketabpezeshki.com 66485457-66963820

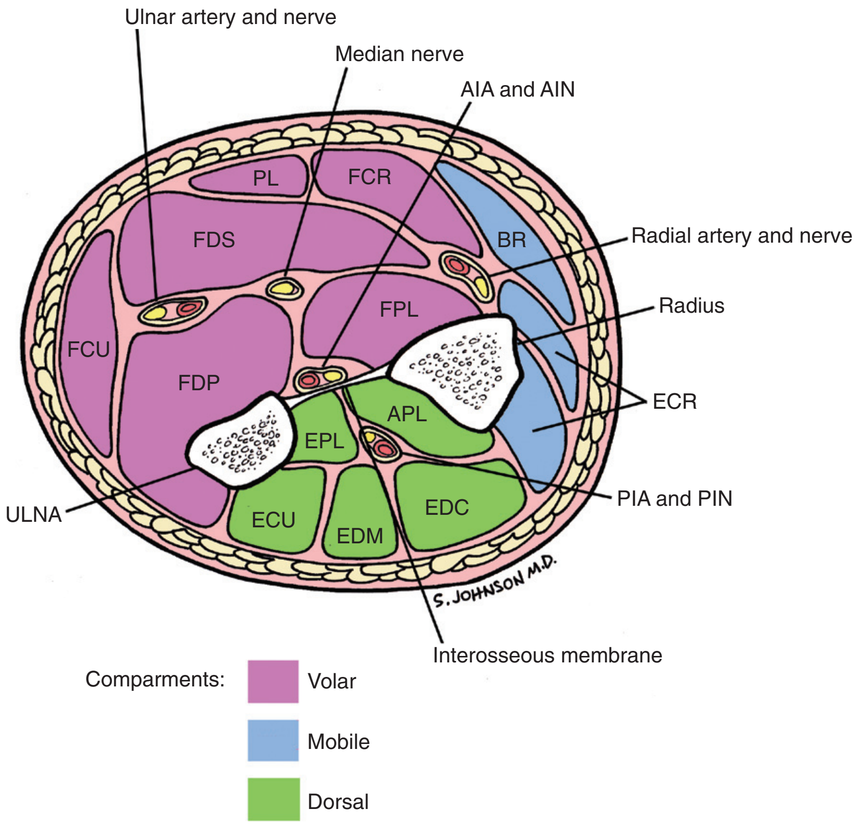

Figure 51-36. Cross section of the forearm demonstrating the compartments and the neurovascular structures. The volar compartment contains the flexor of hands and wrist, including the policis longus (*PL*), the flexor digitorum superficialis *(FDS),* flexor carpi radialis *(FCR),* flexor pollicis longus *(FPL),* flexor digitorum profundus *(FDP),* and flexor carpi ulnaris *(FCU),* as well as the ulnar nerve, ulnar artery, median nerve, radial artery, superficial branch of the radial nerve, anterior interosseous artery *(AIA),* and anterior interosseous nerve *(AIN).* The dorsal and volar compartments are bordered by the interosseous membrane. The dorsal compartment contains finger extensors and the long thumb abductor as well as the posterior interosseous artery *(PIA),* posterior interosseous nerve *(PIN),* the abductor pollicis longus (*APL*), the extensor digiti minimi (*EDM*), extensor carpi ulnaris *(ECU),* extensor pollicis longus *(EPL),* and extensor digitorum communis *(EDC).* The mobile wad, which is often considered to be a third compartment, is composed of the extensor carpi radialis brevis and longus muscles *(ECR)* and the brachioradialis *(BR).* (Courtesy Sonia Johnson, MD.)

Anatomy

The forearm is a unique two-bone structure with the radius and ulna being bound at both ends by a ligamento-capsular structure. The proximal radioulnar joint (PRUJ) is made up of an articulation between the radial head and ulna. The radial head, the primary stabilizer of the forearm combined with the annular, quadrate, radial, and ulnar ligaments, provides strong support at the PRUJ. At the DRUJ, the TFCC and the anterior and posterior radioulnar ligaments support the articulation of the distal radius and ulna.[91] The interosseous membrane further stabilizes the forearm by providing a strong interconnection between the radius and ulna. The ulna is relatively straight and provides the rotational axis for the bowed radius to rotate around through various planes of motion. The supinator, pronator teres, and pronator quadratus muscles insert along the shaft of the radius and ulna to provide their named function, but they also are responsible for the deforming forces in forearm fractures.

The forearm is typically divided into three compartments: volar, dorsal, and mobile wad.[92] The interosseous membrane divides the volar and the dorsal compartments, and the mobile wad is located laterally (Fig. 51-36). The volar compartment, which can be further divided into superficial and deep layers, contains the pronators and flexor muscles of the hands. The radial, ulnar, and anterior interosseus arteries and median, ulnar, and superficial radial nerves are also contained within the volar compartment. The dorsal compartment consists of the extensor muscles of the hand and the posterior interosseous artery and nerve. The mobile wad is located in the proximal lateral aspect of the forearm and contains the brachioradialis, the extensor carpi radialis longus, and the extensor carpi radialis brevis.

CLINICAL FEATURES

Obtaining the history of the mechanism of injury is crucial in the initial assessment of a forearm injury. Physical examination of the forearm injury begins with visual inspection evaluating for swelling along the injured area, obvious deformity, and evidence of lacerations. Gentle palpation of the injured area can assist in localization, reveal crepitus in grossly unstable fractures, and allow assessment of skin turgor in the evaluation of compartment pressure. Significant swelling as well as disproportionate pain, paresthesia, and paleness of skin should alarm physicians regarding development of compartment syndrome. Neurologic evaluation should include careful examination of motor and sensory function of the radial, ulnar, and median nerves. Assessment of the brachial, radial, and ulnar arteries should be part of the vascular examination.

DIAGNOSTIC STRATEGIES: RADIOLOGY

The radiologic evaluation of the forearm injury should begin with the AP and lateral views. It is essential to include both wrist and

www.ketabpezeshki.com 66485457-66963820

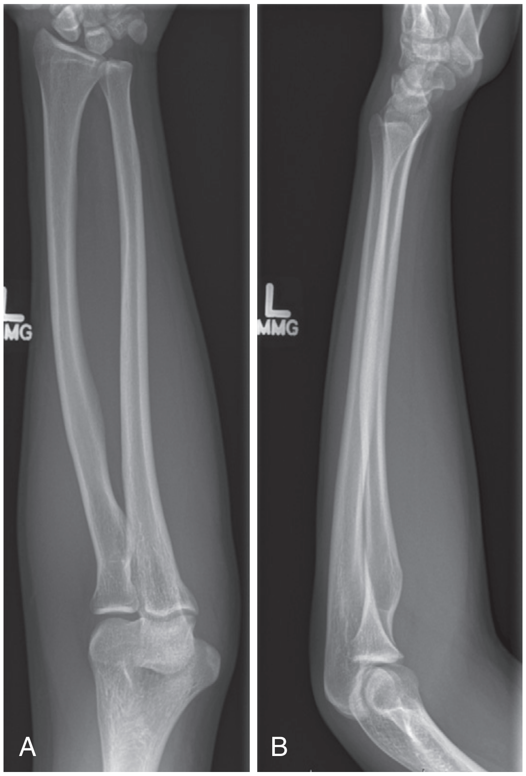

Figure 51-37. Normal anteroposterior **(A)** and lateral **(B)** radiographic views of the forearm. Both bones should be visible for their entire length, and the radiograph should include the wrist and elbow joints.

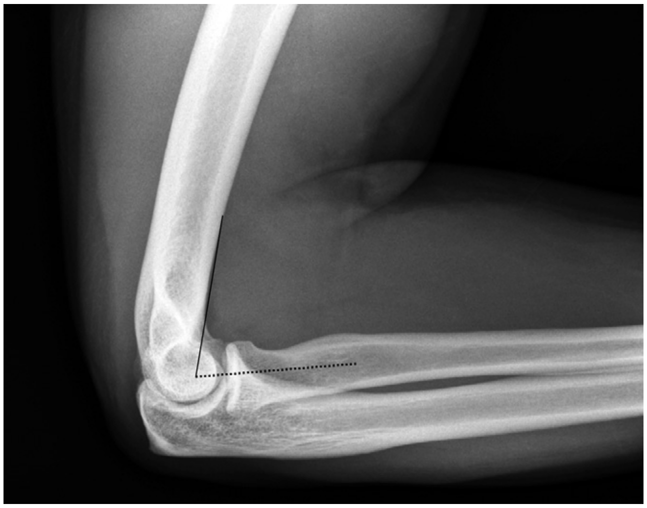

Figure 51-38. Lateral radiographic view of a normal elbow. A line *(dotted)* bisecting the proximal radial shaft also bisects the capitellum.

elbow in the x-ray examination of the forearm to exclude any concomitant injuries to either the DRUJ or PRUJ.

On the normal AP view of the forearm, a medially pointing radial styloid and laterally projecting biceps tuberosity of the proximal radius are visible. On the lateral view, the coronoid process of the proximal ulna points volarly and the ulnar styloid lies dorsally (Fig. 51-37). Any deviation suggests an abnormal rotational or axial deformity. The normal radiologic findings of the forearm, including radiocarpal articulation angle, relationship between radial styloid and ulnar styloid, and normal volar tilt of the radius, are described in the section on radiology of the wrist (earlier).

Injury to the radial head can be evaluated by drawing a mid-axis line through the radial shaft, neck, and head. This radial mid-axis line should intersect the center of capitellum of the elbow on any radiologic view. Any variance from this alignment should raise suspicion regarding radial head dislocation (Fig. 51-38).

CT scans can be useful when there is a suspicion of extension of the fracture into the DRUJ or PRUJ on plain radiography. MRI is the study of choice for evaluation of soft tissues (muscle, tendon, and ligament) of the forearm, including the interosseous membrane. Ultrasound images can also help with evaluation of interosseous membrane injury.[93]

FOREARM FRACTURES

Shaft Fractures of Radius and Ulna

Fractures involving both the radius and the ulna, also known as "both-bone" fractures, are common forearm injuries. Patients often have pain and obvious deformity of the forearm as a result of either minor or major trauma. Careful physical examination is warranted to exclude any associated neurovascular injuries or open fracture. Compartment syndrome should be considered in all patients with this type of injury. Initial radiologic evaluation should include not only AP and lateral radiographs of the forearm, but dedicated wrist and elbow radiographs as well.

After initial evaluation, any open fractures should be immediately irrigated with sterile normal saline to decrease contamination, and a sterile dressing should be applied while operative management is awaited. Any grossly displaced fracture-dislocation should be reduced to improve alignment and prevent impending or ongoing neurovascular injury. Application of a sugar-tong forearm splint should be made with an urgent referral to an orthopedist as long as there is no evidence of open fracture or neurovascular compromise.[94] Because nondisplaced radius and ulna fractures are extremely uncommon, most both-bone fractures of the forearm will eventually require operative management. Common complications of combined radius and ulna fractures are nonunion, malunion, infection, and neurovascular injury.[94]

Ulna Shaft Fractures

Isolated fractures of the ulna shaft, known as "nightstick fractures," are seen frequently in the ED. Patients often have pain and swelling over the medial aspect of the forearm, as the usual mechanism involves raising the arm overhead to protect from a direct traumatic impact. Careful inspection of the skin is necessary; many patients have open fractures, given the superficial position of the ulna directly under the subcutaneous skin. Complete examination should include wrist and elbow examinations to exclude any associated injuries involving the PRUJ or DRUJ. The practitioner should be aware of potential instability at either articulation associated with fractures involving the proximal or distal third of the ulna.

Diagnosis of an ulna fracture is made through the findings on AP and lateral radiographs of the full-length forearm. (Fig. 51-39) Although most isolated ulna fractures are considered stable, those with more than 50% displacement, more than 10 degrees of angulation, involvement of the proximal one third of the ulna, or instability at either the DRUJ or PRUJ are considered unstable fractures.[95] There are no absolute indications for operative management of isolated ulna shaft fracture; however, unstable fractures should be referred to an orthopedist urgently for possible ORIF, as they carry a high risk of function loss, nonunion, malunion, and radioulnar synostosis.[96]

www.ketabpezeshki.com 66485457-66963820

Figure 51-39. Isolated ulna fracture (nightstick fracture). Anteroposterior **(A)** and lateral **(B)** radiographic images show isolated ulnar fracture.

Most stable ulna fractures heal without significant clinical sequelae. Stable fractures can be managed with 6 to 8 weeks of short arm, below-elbow immobilization with interosseous molding to limit radial angulation and prevent forearm rotation. Above-elbow immobilization or long arm casting may be detrimental to the healing process, and they have been associated with nonunion and delayed union.[96]

Monteggia's Fracture

The ulna fractures associated with radial head dislocation are commonly known as *Monteggia's fractures* and account for 1 to 2% of all forearm fractures.[97] In 1814, Giovanni Battista Monteggia specifically described a traumatic lesion involving the fracture of the proximal third of the ulna and anterior dislocation of the radius. In 1974, Bado redefined Monteggia's lesion and classified it to encompass various ulna fractures with concomitant radial head dislocation. The Bado classification divides the injury into four types depending on the location and the angulation of the ulna fracture along with the direction of the radial head dislocation.[98]

Patients with Monteggia's fracture often have fallen on an outstretched hand, resulting in hyperpronation. Direct posterior force on the ulna or a fall on the flexed elbow has been implicated in the mechanism of the injury as well. Typically, patients have edema and tenderness along the fracture site accompanied by a limited range of motion at the elbow and pain with pronation of the forearm. A dislocated radial head may be appreciated on

Figure 51-40. Monteggia's fracture-dislocation. A fracture of the ulna diaphysis with anterior dislocation of the radial head *(arrow)* is shown in this lateral view of the forearm.

palpation. Initial assessment of Monteggia's fracture should include complete neurologic examination because the posterior interosseous nerve (PIN), a deep branch of the radial nerve, can be injured. Because the PIN innervates the finger extensors along with the supinator, PIN injury is often manifested by weakness or paralysis of the thumb and/or finger extension.[99]

The radiograph of the forearm reveals the obvious ulna fracture that often overshadows the subtle radial head dislocation (Fig. 51-40). A chronic, irreducible radial head dislocation can occur as a result of delay in diagnosis. Drawing of the radiocapitellar line through the head of the capitellum can prevent the overlooking of a proximal dislocation. The line should intersect the distal third of the capitellum on all views and confirm correct alignment.

Treatment of Monteggia's fracture depends on the age of the patient. Pediatric patients with this type of injury can be treated conservatively with long arm casting in supination with acceptable reduction. However, most adult patients with this type of fracture should be referred to an orthopedic surgeon urgently for ORIF. Complications of Monteggia's fracture include malunion, nonunion, synostosis, stiffness, and nerve palsy. Early diagnosis and treatment of Monteggia's fracture are crucial in achieving good outcomes.[97]

Galeazzi's Fracture

Galeazzi's fracture refers to a fracture of the middle to distal third of the radius associated with injury to and dislocation of the DRUJ. It accounts for 3 to 7% of all forearm fractures.[100] Typically, Galeazzi's fracture results from a fall or motor vehicle collision as the patient attempts to brace for impact by outstretching the hand in pronation. A direct blow to the dorsolateral aspect of the forearm is less common but well recognized as a mechanism of injury for Galeazzi's fracture as well. Galeazzi's fracture is often overlooked as a simple radius fracture, yet it often results in diminished forearm range of motion, weakness, and chronic pain.

In addition to the radiographic imaging, history and clinical examination play a crucial role in diagnosis of Galeazzi's fracture, as injuries to the DRUJ may not be obvious. Patients with Galeazzi's fracture have deformity at the site of the fracture associated with swelling and tenderness. Meticulous attention is required in examining the wrist to evaluate for stability of the DRUJ. Instability of the DRUJ can range from obvious prominence of the ulnar head (associated with the subluxation or dislocation) to tenderness elicited at the wrist, which can be a subtle sign of DRUJ ligament injury.

AP and lateral radiographs of the entire forearm and wrist are essential to diagnose Galeazzi's fracture. Besides the obvious fracture of the radius at the middle to distal third, there will be other radiographic findings. On the AP view of the forearm, the space

www.ketabpezeshki.com 66485457-66963820

Figure 51-41. Galeazzi's fracture-dislocation. The anteroposterior **(A)** and lateral **(B)** views of the forearm show an obvious fracture of the distal third of the radius with severe displacement and an associated dislocation of the distal radioulnar joint *(arrow)*.

between the distal radius and ulna is widened (greater than 2 mm) and the radius appears relatively shortened. In the lateral view, the dorsally angulated fracture of the radius can cause a dorsal displacement of the ulnar head. A fracture at the base of the ulnar styloid should raise the suspicion for DRUJ interruption (Fig. 51-41). Although not all radius shaft fractures are associated with DRUJ injury, Ring and colleagues showed that at least 25% of all patients with radius fractures had DRUJ dislocation.[100] Therefore patients with radius shaft fracture should be referred to an orthopedist for close follow-up.

Conservative management of Galeazzi's fracture in adults has been associated with poor outcomes. Because of the deforming forces from different forearm muscles and loss of stability at the DRUJ, displacement of the alignment in the cast occurs despite successful initial reduction. Galeazzi's fracture has been termed a "fracture of necessity" to imply that surgical intervention is crucial for achievement of an ideal anatomic position and acceptable functional outcomes.[101,102] Any patient with this fracture should be referred to an orthopedist urgently for ORIF of the radius and associated repair of DRUJ. In contrast, conservative treatment with closed reduction and long arm casting has been successful in children and rarely requires surgical intervention.[103] Along with the common complications associated with forearm fractures such as malunion and nonunion, the occurrence of subluxation and dislocation of the DRUJ can result in limited motion and chronic pain.[104]

Essex-Lopresti Lesion

The *Essex-Lopresti lesion,* or longitudinal radioulnar disassociation, refers to an unstable forearm as a result of a triad of injuries to the radial head, disruption of the interosseous membrane, and violation of the DRUJ. The patient often has fallen on an outstretched hand, resulting in transmission of a large axial loading force from the wrist to the elbow. Consequently, the radial head, the primary forearm stabilizer, is fractured and displaced proximally. Disruption of the interosseous membrane and DRUJ also occurs and compromises the stability of the forearm.[105] In addition to localized pain along the elbow from radial head fracture, patients with the Essex-Lopresti injury have wrist and forearm pain along with grip and pronation weakness. The diagnosis of the Essex-Lopresti lesion remains elusive, as the standard AP and lateral views of the forearm often reveal only isolated radial head fracture. The integrity of the interosseous membrane is difficult to assess based on the plain film. Subtle findings of positive ulna variance and a widened DRUJ are suggestive of longitudinal radioulnar dissociation. Obtaining a grip view and comparing the injured wrist with the contralateral wrist can be helpful in diagnosing an Essex-Lopresti injury. MRI is the study of choice when clinical suspicion for Essex-Lopresti injury is high; however, ultrasound has been used more frequently recently to evaluate the integrity of the interosseous membrane.[93,106]

Once the diagnosis of Essex-Lopresti injury has been made, the patient should be referred to an orthopedic surgeon for further surgical intervention. Many strategies have been proposed to repair Essex-Lopresti lesions, and the treatment option varies depending on the chronicity of the injury. Radioulnar synostosis and loss of forearm rotation can result from longitudinal disassociation.[106]

Pediatric Forearm Fractures

Forearm fractures are the most common orthopedic injuries in children.[107] Many patients have a painful, swollen, and possibly deformed forearm after having fallen onto the outstretched hand. In general, forearm fractures are divided into three categories: greenstick (or incomplete fractures), complete fractures, and plastic deformation. Depending on the growth plate maturity, fracture pattern, anatomic location of the fracture, degree of angulation, and displacement, treatment options vary.[108]

The principal goal in treating pediatric forearm fracture is to achieve bony healing and preservation of function while avoiding surgery and minimizing complications. Any fracture with deformity in a pediatric patient should be reduced to anatomical alignment, but a clinician should also consider the potential correction of the bone remodeling. Usually, younger patients (younger than 10 years) with fractures near the physis have the greatest potential for remodeling. These principles govern the acceptability of fracture reduction, and in general, an angulation of less than 10 degrees is often considered acceptable.[109]

Greenstick fractures or incomplete fractures usually result from torsional mechanisms resulting in disruption on one side of the cortex and traumatic bowing. Although the utility of completing the greenstick fracture at the site of bowing remains controversial, patients with greenstick fracture should be referred to an orthopedic surgeon for closed reduction under adequate anesthesia.[90,110]

A complete fracture is complete disruption of the cortex and requires an orthopedic referral for closed reduction (Fig. 51-42). Surgical indications for forearm fractures include open fractures, injuries resulting in neurovascular compromise, and irreducible or unstable fractures. After application of a long arm cast for immobilization, serial radiographs are obtained to ensure adequate reduction. Common complications of forearm fractures, such as malunion and nonunion, are uncommon owing to rapid healing among the pediatric population, but there is an increase in risk of refracture within the first 12 months.

Plastic deformation refers to bending of the bone, resulting in traumatic bowing without obvious fracture (Fig. 51-43). Initially,

www.ketabpezeshki.com 66485457-66963820

Figure 51-42. Pediatric forearm fracture. Anteroposterior **(A)** and lateral **(B)** radiographic views show radial and ulnar shaft fractures with dorsal angulation.

Figure 51-43. Plastic deformation. Lateral radiograph of the forearm shows severe plastic deformation of radial and diaphyseal fracture of the ulna.

plastic deformation was described exclusively in children, but adults with such injury pattern have been recognized.[111] Typically, patients with plastic deformation are younger than 10 years of age and have little deformity, localized tenderness and swelling, and reduced pronation and supination range of motion. The radiograph may show subtle abnormal bowing of the radius or ulna shaft with narrowing of the interosseous space. Patients with plastic deformation should be promptly referred to an orthopedist for closed reduction and long arm casting. Although most will achieve a good functional outcome, some may require surgery if the bowing remains excessive.

Compartment Syndrome

Acute compartment syndrome of the forearm has been associated with multiple causes. In the pediatric population, subcondylar fractures have been commonly linked to compartment syndrome of the forearm, whereas distal radius fracture remains the most common cause in adults.[112] If the entity is not recognized early and is left untreated, it can result in permanent contracture of the hand and wrist, known as *Volkmann's ischemic contracture.*

There are many theories on the exact mechanisms of the compartment syndrome, but tissue hypoperfusion and damage to the muscles and nerves are its end results. Classically, patients may have a tense edema of the forearm with blisters associated with the traditional five *P*s of compartment syndrome: pain, pallor, pulselessness, paralysis, and paresthesia.[113] However, absence of pulse is a late finding of the compartment syndrome, and a practitioner should not wait for presence of all five *P*s before suspecting compartment syndrome. One should have a low threshold for obtaining compartment pressures when this syndrome is suspected. If the compartment pressure is greater than 30 mm Hg or within 20 mm Hg of the diastolic pressure in the presence of other characteristic clinical findings, emergency surgical consultation is mandatory for surgical decompression.[114] Early diagnosis of compartment syndrome and prompt fasciotomy have been associated with good functional outcomes.

KEY CONCEPTS

- In the setting of acute trauma, there is a high incidence of occult fractures of the wrist. For instance, plain radiographs fail to detect 15% of scaphoid fractures. Because of the associated risk of malunion, nonunion, and AVN when diagnosis is delayed, when radiographs are negative and pain persists, immobilization is recommended. A thumb spica is usually added in the setting of suspected scaphoid and other carpal fractures. Repeat physical examination, radiographs, or advanced imaging (e.g., MRI, CT, or ban scan) is indicated if symptoms persist.
- Triquetral fracture is best seen on the standard lateral view of the wrist as a small dorsal avulsion fragment, although a more oblique pronated lateral view may be necessary to visualize it.
- Lunate dislocation results in a characteristic triangular appearance of the lunate on the PA view ("piece of pie sign") owing to the rotation of the lunate in a volar direction. This rotation also is visible on the lateral view of the wrist, on which the lunate looks like a cup tipped forward and spilling its contents into the palm ("spilled teacup sign").
- On the PA radiograph of the wrist, three arcs, known as *Gilula's lines,* and equal spacing between carpus bones (1-2 mm), known as *parallelism,* assist in the radiographic diagnosis of carpus injury.

www.ketabpezeshki.com 66485457-66963820

- Colles' fracture reduction attempts to restore radial length and ulnar variance (<2 mm) and correct dorsal angulation to the normal volar tilt (0-20 degrees). Closed reduction is commonly performed with use of pain control, local analgesia (hematoma block), regional anesthesia, or procedural sedation.
- Anteroposterior and lateral views of the forearm must include the wrist and elbow joints because radial and ulnar forearm fractures may be associated with proximal, radial, or DRUJ dislocations.

ACKNOWLEDGMENT

We would like to thank the previous authors, Karen G. H. Woolfrey, Michael Woolfrey, and Mary A. Eisenhauer, for their work and contributions to this chapter.

Chapter 52

Humerus and Elbow

Thom A. Mayer

PERSPECTIVE

Because injuries in the region of the elbow have a high potential for complications and residual disability, early recognition of neurovascular and soft tissue complications improves the outcome in many of these injuries. Coordination between the emergency physician and the treating orthopedist is essential, particularly because new options are emerging for many of these injuries.

Anatomy

The humerus is a long bone that articulates proximally at the shoulder with the glenoid of the scapula to form the glenohumeral joint and distally with the radius and ulna to form the three-way elbow joint. The upper end of the humerus, the humeral head, is shaped like a near hemisphere. Adjacent to the humeral head are two bony prominences, the greater and lesser tuberosities. Between these, on the anterolateral aspect of the humerus, runs the bicipital groove. The shaft of the humerus extends from the upper border of the insertion of the pectoralis major muscle superiorly to the supracondylar ridges inferiorly. The shaft is cylindrical on cross section in the upper half and tends to become flat in the distal portion in an anteroposterior direction. Three surfaces are described. The anterolateral surface presents the deltoid tuberosity for the insertion of the deltoid muscle, and below this is the radial soleus, which transmits the radial nerve and profunda artery. The anteromedial surface forms the floor of the intertubercular groove, but it normally has no outstanding surface markings. The posterior surface is the origin for the triceps and contains the spiral groove.

The bony anatomy of the distal humerus and elbow is diagrammed in Figure 52-1. The distal end of the humerus tapers into two columns of bone, the medial and lateral condyles. Between the condyles, the bone thins, and the recess created is the coronoid fossa. The more proximal nonarticular portions of the condyles are the epicondyles. Just proximal to the epicondyles, the supracondylar ridges run up each side of the humerus. Collectively, these areas serve as points of origin for the muscles of the forearm. The wrist flexors originate from the medial epicondyle, and the wrist extensors originate from the lateral epicondyle. Fractures of the distal humerus often result in fragment displacement because of the pull of these strong forearm muscles on attachment sites.

The bony anatomy of the elbow allows for two complex motions: flexion-extension and pronation-supination. The elbow is composed of three articulations within a common joint cavity. The trochlea is the articular surface of the medial condyle and articulates with the deep trochlear notch of the ulna formed by the olecranon inferiorly and posteriorly and by the coronoid process anteriorly. This articulation permits hinged flexion and extension at the elbow. The articular surface of the lateral condyle is the capitellum, which permits the radius to hinge on the elbow. The proximal radius consists of a disklike head supported by the smooth narrow radial neck. The radial head articulates with the capitellum of the humerus and with the radial notch of the ulna.

Four ligamentous structures are important in evaluating elbow injuries (Fig. 52-2). The radial head is held in place by the annular ligament and the adjacent radial collateral ligament. Rotation of the radial head within the confines of the fibrous annular ligament permits pronation and supination. In addition, the ulnar collateral ligament and anterior capsule add stability to the joint. Fracture or dislocation of the joint may severely damage the ligamentous structures.

The soft tissues of the upper arm are divided into two compartments: anterior and posterior. The anterior compartment contains three muscles—the biceps brachii, the brachialis, and the coracobrachialis—and the brachial artery, median nerve, musculocutaneous nerve, and ulnar nerve. The only two structures contained in the posterior compartment are the triceps brachii muscle and the radial nerve.

The neurovascular structures of this area are shown in Figure 52-3. The brachial artery, which is the continuation of the axillary artery, travels with the median nerve in the anterior compartment of the upper arm. It enters the antecubital fossa and bifurcates into the radial and ulnar arteries.

One important anatomic variation is the presence of a supracondylar process (in approximately 2.5% of cases) just proximal to the medial epicondyle (Fig. 52-4). When the supracondylar process is present, the median nerve and brachial artery must traverse behind this process, then forward between a fibrous band connecting the process to the epicondyle. Median nerve symptoms may develop if this process is fractured or if an injury causes swelling in the vicinity of the supracondylar process.

The radial nerve leaves the axilla and spirals posteriorly around the humerus between the heads of the triceps in the radial groove. It reenters the anterior compartment of the arm laterally, crossing the elbow anterior to the lateral epicondyle to innervate the extensors of the wrist and fingers. Because of its close relationship to the shaft of the humerus, the radial nerve is particularly susceptible to injury with midshaft humeral fractures. Fixed in position by the intermuscular septum, the nerve may become trapped between fracture fragments, particularly when reduction is attempted.

The ulnar nerve runs parallel to the median nerve. Halfway down the arm, it penetrates the intermuscular septum to run along the medial aspect of the triceps muscle in the posterior compartment. It enters the forearm by passing behind the medial condyle. Fractures in the vicinity of the medial condyle place this nerve at considerable risk for injury.

Three elbow bursae are clinically important. The olecranon bursa is located between the olecranon and the skin posterior to the joint. This bursa provides protective padding and allows smooth movement of the skin over the olecranon. Because of its position, it is often a site of traumatic or infectious bursitis. The radiohumeral bursa provides for smooth movement over the radial head with supination and pronation. A third bursa cushions the biceps tendon from the radius during flexion of the elbow. As evident by the descriptions of these structures, all are vulnerable when significant skeletal injury occurs in this region.

CLINICAL FEATURES

History

A history detailing musculoskeletal complaints includes a description of any pain in terms of quality, duration, location, palliative and provocative activities, severity, and radiation. Past medical history and occupational factors are important in chronic problems. For traumatic injuries, a detailed account of the incident is important because it provides information about the mechanism of injury and some estimate of the energy delivered. Subjective complaints of numbness or weakness distal to the injury are important clues to possible neurovascular injury. In dealing with injuries in children, the possibility of nonaccidental trauma needs to be considered.

Physical Examination

Inspection of the upper extremity is important, but manipulation of the painful extremity should be minimized and postponed to the end of the examination whenever possible. This is especially important with children. A great deal of useful information can

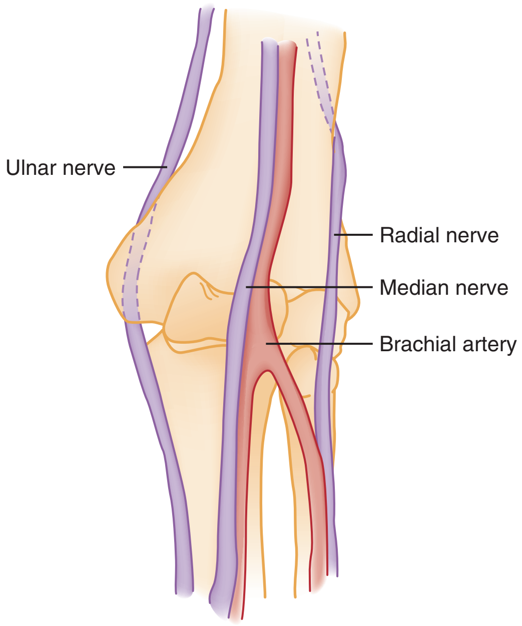

Figure 52-3. Neurovascular structures of elbow region. Volar surface of left elbow is shown.

www.ketabpezeshki.com 66485457-66963820

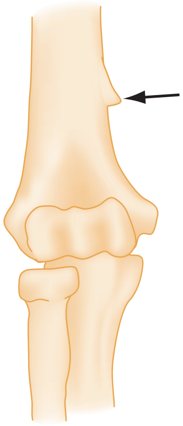

Figure 52-4. Supracondylar process of the humerus *(arrow)*. Volar surface of right elbow is shown.

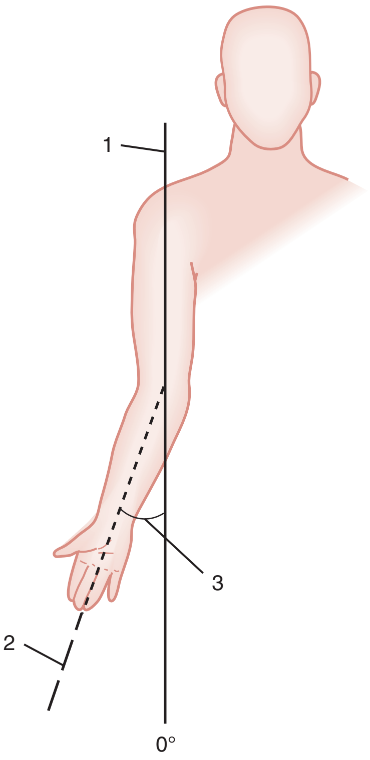

Figure 52-5. Carrying angle *(3)* is formed by intersection of lines drawn parallel to long axis of humerus *(1)* and ulna *(2)*. (Adapted from Ruiz E, Cicero J: Emergency Management of Skeletal Injuries. St Louis: Mosby; 1995.)

be gathered by simple inspection and comparison with the contralateral limb. The position in which the extremity is held should be noted. In children with extension-type supracondylar fractures, the arm is held at the side and has a characteristic S-shaped configuration, whereas with flexion-type supracondylar fractures, the forearm is supported with the opposite hand with the elbow flexed to 90 degrees. Patients with radial head subluxation have the elbow only slightly flexed and hold the forearm in pronation.

Deformity is evidence not only of significant injury, but also of the type of injury. Increased prominence of the olecranon suggests a posterior dislocation of the elbow or extension supracondylar fracture, whereas loss of the normal olecranon prominence indicates anterior dislocation or flexion supracondylar fracture. The extremity also should be inspected for wounds that may indicate an open fracture, evidence of swelling, and change in color of the distal extremity.

One special aspect of the elbow examination is the determination of the carrying angle, the normal outward angulation of the extended forearm at the elbow. This angle allows the long axes of the humerus and forearm to become superimposed when the elbow is flexed (Fig. 52-5). This angle varies from 5 to 20 degrees in adults, with men having less angulation than women. Measurement of the carrying angle is helpful in assessing subtle supracondylar fractures in children. As shown in Figure 52-6, lines drawn parallel to the shafts of the humerus and ulna intersect to form an angle with a mean measurement in children of 13 degrees, although this angle varies widely.[1] A difference in carrying angles of greater than 12 degrees (from one side to the other for a particular individual) is associated with fractures. However, the carrying angle is used primarily for assessing the adequacy of reduction or the results of fracture healing rather than for acute diagnosis, because it is difficult for children to fully extend the arm during the initial evaluation for this measurement to be obtained.

The vascular status of the extremity is of highest priority. Brachial, radial, and ulnar pulses should be palpated and documented. The ulnar pulse is not palpable in some normal people. Although brisk capillary refill suggests adequate tissue perfusion, a handheld Doppler device often is required to evaluate major vessel flow if significant swelling is present or if the pulses are not palpable. Any suggestion of arterial injury requires immediate investigation. Poor perfusion may result from direct arterial injury, compression or kinking in the instance of significant displacement from a fracture or dislocation, or compartment syndrome. Passive extension of the fingers produces severe pain in the forearm in the presence of flexor (volar) compartment ischemia. Of the five *Ps* associated with arterial occlusion (pain, paresthesia, pallor, pulselessness, and paralysis), pain is the only dependable early sign of compartment syndrome. Orthopedic consultation and measurement of compartment pressures should be considered for patients who have pain disproportionate to their injury. Other modalities used to evaluate vascular status while the orthopedist is being called in include measurement of the ankle-brachial index and color flow Doppler.

Neurologic evaluation includes assessment of the radial, median, and ulnar nerves. After evaluation of neurovascular function, all bony prominences are palpated, and areas of tenderness are noted carefully and documented. Crepitus and bony deformities are unusual in the absence of fracture or dislocation. Bony crepitus associated with pain in an acutely injured limb is virtually diagnostic of a fracture. The radial head specifically should be palpated for tenderness, and any noticeable effusion should be noted.

The range of motion of the elbow in all planes (i.e., flexion-extension and pronation-supination) should be determined and documented. With the forearm supinated, the normal range of motion is 0 degrees in full extension to 150 degrees in full flexion. A mild degree of hyperextension is normal in some individuals and should be symmetrical. With the elbow flexed at 90 degrees and the thumb facing up, the forearm normally supinates and pronates 90 degrees. Range-of-motion testing may be impossible with severe injuries and can be postponed until after radiographic evaluation, avoiding manipulating fractures and dislocations. Any manipulation of the extremity is followed by reexamination because neurovascular injury has been reported with nearly every therapeutic procedure.

Radiographic Findings

Whereas most elbow and humerus injuries are evaluated radiographically, occasionally history and clinical examination alone are sufficient (e.g., radial head subluxations). Although clinical

www.ketabpezeshki.com 66485457-66963820

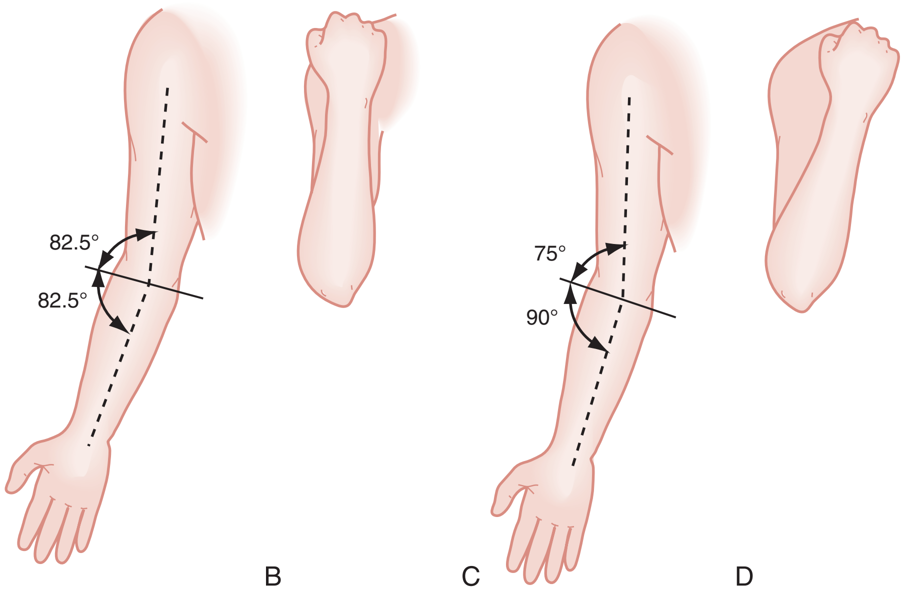

Figure 52-6. **A,** The axis of the elbow joint bisects the angle formed by the long axes of the humerus and forearm. **B,** This allows these axes to become superimposed when the elbow is flexed. **C,** If the axis of the elbow joint was perpendicular to the long axis of the forearm, the respective axes would diverge when the elbow was flexed, as shown in **D.**

decision rules for the elbow have not been validated, it is reasonable to perform radiography when there is significant limitation in range of motion, obvious deformity, joint effusion, or significant tenderness over any of the bony prominences or the radial head. In the absence of these, radiographic studies are optional. The threshold for radiography should be much lower in pediatric populations owing to the presence of open growth plates and limitation in the physical examination with the exception of children with obvious nursemaid's elbow (radial head subluxation).

Routine views of the elbow include at least the anteroposterior and lateral views, with consideration given to obtaining oblique views for certain injuries. Anteroposterior and oblique views are taken with the elbow extended. The lateral view is taken with the elbow in 90 degrees of flexion and the thumb pointing upward. Positioning of the elbow is important because anything but a true lateral view makes accurate interpretation of soft tissue findings and alignment difficult. Corresponding views of the opposite extremity may be helpful, especially for children, but should not be ordered routinely.

Many fractures in the elbow region are obvious on plain film, with cortical disruption, angulation, or displacement of fragments. Minor fractures can be subtle and may be missed. Special attention to the contour of the radial head and the fat pads reduces the risk of missing fractures. The normal cortex of the radius is smooth and has a gentle continuous concave sweep. If consistent with history and physical findings, any disruption of this smooth arc is considered evidence of fracture. Abnormalities within the soft tissues on elbow films are particularly important and may be the only radiographic sign of a fracture. Normally, fat surrounding the proximal elbow joint is hidden in the concavity of the olecranon and coronoid fossae. The normal elbow has only a narrow strip of lucency anteriorly (the anterior fat pad), and a posterior fat pad is not visible on radiographs. Injuries that produce intra-articular hemorrhage cause distention of the synovium and displace the fat out of the fossa, making the posterior fat pad visible on lateral radiographic views. The anterior fat pad also is altered by this swelling, becoming more prominent and taking the shape of a spinnaker sail from a boat: "sail sign" (Fig. 52-7). In the setting of trauma, more than 95% of patients with the "posterior fat pad" sign have intra-articular skeletal injury. These soft tissue findings occur even with subtle fractures, and when they are present in the setting of trauma, an occult fracture is considered to be present even when not visible on radiographs. In adults, a radial head fracture is implied, whereas in children a supracondylar fracture is the more likely underlying injury. In the absence of trauma, the presence of a fat pad suggests other causes of effusion (e.g., gout, infection, bursitis). The fat pad signs may be absent in fractures where the injury is severe enough to rupture the capsule.

The anterior humeral line is a line drawn on a lateral radiograph along the anterior surface of the humerus through the elbow. Normally, this line transects the middle third of the capitellum (Fig. 52-8). With an extension supracondylar fracture, this line either transects the anterior third of the capitellum or passes entirely anterior to it. The abnormal relationship between the anterior-humeral line and capitellum may be the only evidence of a minimally displaced supracondylar fracture and is a presumptive finding of a fracture.

Another diagnostic aid in evaluating radiographs of possible supracondylar fractures in children is the determination of Baumann's angle. As shown in Figure 52-9, the intersection of a line drawn on the anteroposterior film through the midshaft of the humerus and the growth plate of the capitellum defines an angle of approximately 75 degrees. In normal children, Baumann's angle is the same in both elbows, and it has been suggested that a comparison between the injured and uninjured sides be used to assess the accuracy of reduction. An increase in Baumann's angle indicates medial tilting of the distal fragment. Alteration in Baumann's angle is thought to predict the final carrying angle when the fracture heals, although there is controversy regarding its reliability.[2]

Radiographic evaluation of the elbow in children is difficult because of the presence of multiple ossification centers (Fig. 52-10). Table 52-1 lists the typical age of first appearance and fusion of ossification centers, which gives rise to the *CRITOE* acronym:

- Capitellum
- Radial head
- Internal (medial) epicondyle
- Trochlea
- Olecranon
- External (lateral) epicondyle

Comparison views of the uninjured elbow are often helpful in distinguishing fractures from the normal epiphyses and ossification centers.

Management

General management principles for humerus and elbow injuries are similar to those for other orthopedic injuries. Limb-threatening conditions, such as vascular injury, are addressed immediately by reduction of fractures or surgical exploration. The limb should be splinted in a position of comfort, and appropriate analgesia should be provided. Antibiotics are administered for suggested open fractures. Prolonged immobilization of the elbow frequently results in stiffness of the joint that requires extensive physiotherapy to restore normal function. For this reason, range-of-motion exercises are begun early in the convalescent period, often before a fracture has healed completely.

FRACTURES

Injuries in the region of the shaft of the humerus and about the elbow fall into several categories (Box 52-1). Emergency department (ED) management varies with location and type of fracture or dislocation. Supracondylar fractures of the humerus in children are usually described according to the Gartland classification (Box 52-2).

Box 52-2 Gartland Classification for Supracondylar Fractures in Children

Type I—Minimal or no displacement
Type II—Displacement of the fracture, but with the posterior cortex intact
Type III—Displaced, no cortical contact
Type IIIA—No rotation of the fracture
Type IIIB—Rotation present

Fractures of the Shaft of the Humerus

Pathophysiology

Fractures of the humeral shaft commonly result from a direct blow to the arm, such as occurs during a fall or motor vehicle collision. Severe twisting of the arm or a fall on an outstretched hand can also produce this type of fracture. Fractures produced by violent muscle contraction, such as occurs when a javelin or baseball is thrown, also are reported.[3] Motion of the humerus is controlled by several muscle groups, which also influence the fracture pattern of the humeral shaft. If the fracture is located proximal to the attachment of the pectoralis major, the proximal fragment of the humerus abducts and rotates internally owing to the action of the rotator cuff, whereas the distal fragment is displaced medially by the pectoralis major (Fig. 52-11A). If the fracture occurs below the pectoralis major insertion but above the deltoid insertion, the distal fragment is displaced laterally by the deltoid muscle, and the proximal fragment is displaced medially by the pull of the pectoralis major, latissimus dorsi, and teres major muscles (Fig. 52-11B). In fractures occurring distal to the deltoid insertion, the proximal fragment is abducted by the deltoid, and the distal fragment is proximally displaced (Fig. 52-11C). The shaft of the humerus most commonly fractures in the middle third in a transverse fashion (Fig. 52-12).

Clinical Features

The patient reports localized pain, often severe in nature. The arm is visibly swollen and cannot be used. When a fracture is complete, bony crepitus is felt in the shaft of the humerus with any manipulation of the arm. The arm may be shortened or rotated, depending on the displacement of the fracture fragments. When the fracture is incomplete, the skeleton is tender to palpation and swollen, but not otherwise deformed. A complete neurovascular examination is indicated. Attention should be directed to radial nerve function because injury to this nerve is the most common complication associated with humeral shaft fractures.

Radiographic findings are confirmatory. Studies routinely should include the shoulder and elbow joints. The humerus is a common site for benign tumors, unicameral cysts, and primary bone malignancies. The humeral shaft also is a common site for metastatic disease. Thinning of the cortex and abnormal osteoblastic or osteoclastic activity are evidence of a pathologic fracture (see Fig. 52-12). These fractures do not heal without concomitant treatment of the underlying pathologic condition.

Management

Closed fractures that are isolated injuries are treated conservatively with a high degree of success. Elaborate attempts at fracture reduction and external immobilization are unnecessary and sometimes detrimental to healing. Humeral shaft fractures remain surrounded by a richly vascularized envelope of muscle so that fracture reduction is accomplished most easily with the aid of gravity and muscle balance. Fractures that are nondisplaced or minimally displaced are immobilized by adding a coaptation, or "sugar-tong," splint, to the sling and swathe (Fig. 52-13). This is accomplished by first padding the extremity, then carrying a long plaster splint from the lateral side of the shoulder, down the lateral aspect of the upper arm, around the elbow with the elbow flexed, and then up the inner aspect of the arm to the axilla. The sugar tong is wrapped in an elastic bandage, and a sling is used to support the arm in 90 degrees or less of flexion. The weight of the

www.ketabpezeshki.com 66485457-66963820

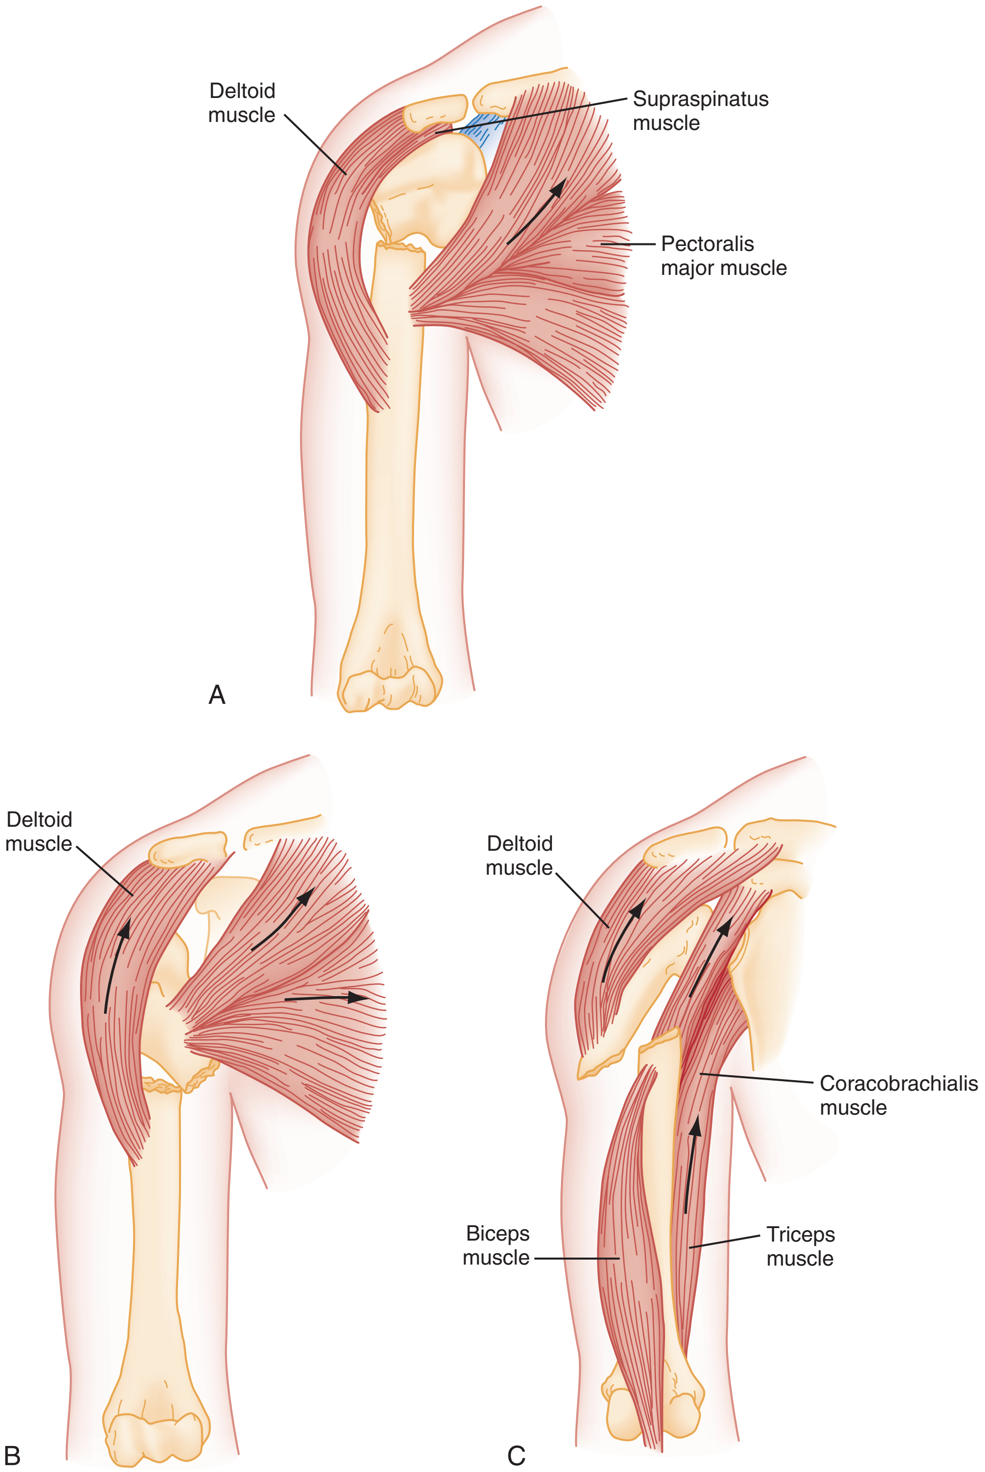

Figure 52-11. Influence of muscles on displacement of humeral shaft fractures based on fracture location. **A,** Fracture is proximal to the attachment of the pectoralis major muscle. **B,** Fracture is between insertion of the pectoralis major and deltoid muscles. **C,** Fracture is distal to the deltoid insertion.

splint aided by gravity applies traction while it immobilizes the fracture. Some authorities use the coaptation splint for only the first 10 to 14 days of treatment, followed by a functional brace.

If the fracture is grossly displaced or comminuted, the hanging cast technique sometimes is used. This technique is especially effective with spiral fractures. The cast is lightweight, applied at least 1 inch proximal to the fracture site, and extends to the distal palmar crease of the hand. The elbow is flexed 90 degrees, and the wrist is placed in the neutral position. The sling is attached through a loop at the wrist. Angulation is corrected by placing the plaster loop on the dorsal aspect of the cast (to reduce lateral angulation) or on the volar side of the cast (to reduce medial angulation). Anterior or posterior angulation is corrected by altering the length of the sling apparatus (Fig. 52-14). Care is taken not to make the cast too heavy because this would distract fracture fragments. The hanging cast has the disadvantage of requiring gravity for traction and requires that the patient remain upright at all times, including during sleep, a situation that many patients find intolerable.

www.ketabpezeshki.com 66485457-66963820

Figure 52-12. Pathologic fracture of proximal humerus.

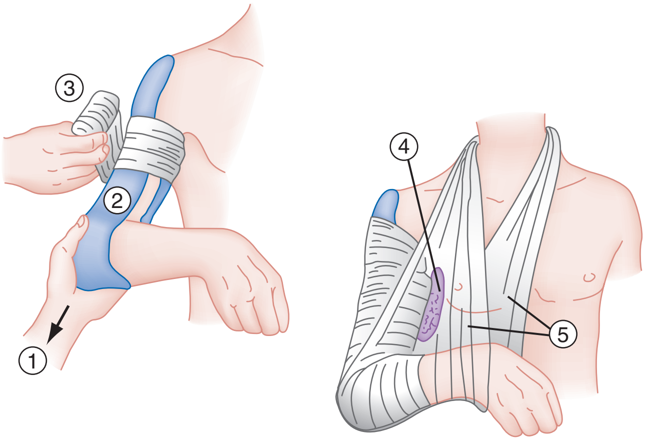

Figure 52-13. Sugar-tong splint for humeral shaft fractures. Gentle traction is applied *(1)* as the splint is placed *(2)* from over the deltoid laterally, under the elbow, and up into the axilla. An elastic wrap holds the splint in place *(3)*. The axilla must be padded *(4),* and a sling is used *(5)*. (Adapted from Connolly JF: DePalma's Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1981.)

Neurovascular examination should be repeated and documented after the application of any splint or cast, because loss of nerve function from entrapment of the nerve between fragments can occur after these interventions.

The use of open reduction and internal fixation (Fig. 52-15) has been more frequent recently and is necessary in certain circumstances, including open fractures, presence of multiple injuries that preclude mobilization, bilateral fractures, poor reduction, poor patient compliance, failure of closed treatment, and fractures through pathologic bone.[4,5] Isolated radial nerve palsy usually is assumed to be a neurapraxia and is managed nonoperatively. Exploration and internal fixation are indicated, however, if the radial nerve palsy develops after manipulation because this is highly suggestive of nerve entrapment.[4]

All patients with humeral shaft fractures should be referred to an orthopedic surgeon for close follow-up monitoring. When

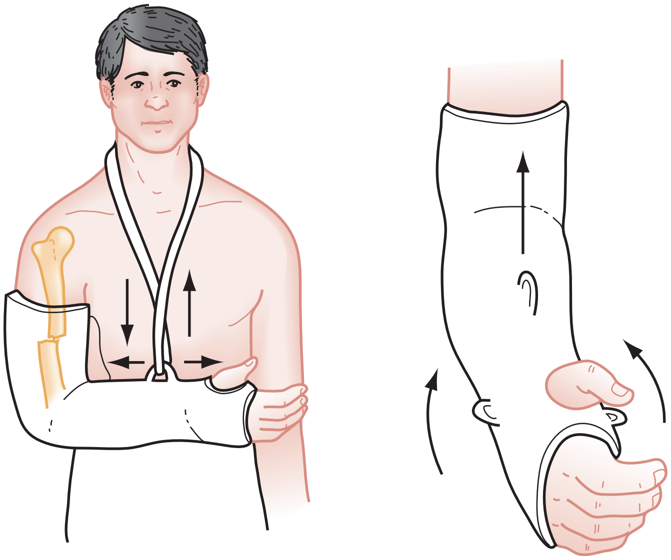

Figure 52-14. Hanging cast technique.

dependency casting is used, follow-up evaluation within 24 to 48 hours is recommended to be certain that the alignment has been maintained. Emergent referral to an orthopedist is recommended for patients with evidence of radial nerve injury, severely displaced or comminuted fractures, open fractures, or fractures associated with forearm fractures in the same extremity.

Complications

The most common complication, radial nerve injury, occurs in 20% of humerus fractures. This nerve injury is most often a benign neurapraxia that resolves spontaneously in most patients, although recovery may take several months. Patients should be advised of this possible complication, with instructions to contact their orthopedist or return to the ED for evaluation if this occurs. Radial nerve injuries associated with penetrating trauma or open fractures are likely to be permanent and usually warrant operative exploration. Median and ulnar nerve injuries are rarely seen, usually in the presence of penetrating trauma. Injuries to the brachial artery occur rarely, and, if clinically suggested, angiography or other vascular studies should be considered.

Fractures of the Distal Humerus

Supracondylar Fractures

Distal humerus fractures that occur proximal to the epicondyles are called *supracondylar fractures.* This type of fracture is almost exclusively an injury of the immature skeleton, with a peak incidence in children 5 to 10 years old[6] This injury rarely occurs after age 15 and accounts for approximately one half of all elbow fractures and one third of pediatric limb fractures. In children, the tensile strength of the collateral ligaments and joint capsule of the elbow is greater than that of bone. In adults, the reverse is true, and a posterior elbow dislocation is sustained instead. Supracondylar fractures are classified as either extension or flexion fractures, depending on the mechanism of injury and the displacement of the distal fragment. Of these injuries, 98% are of the extension type.

Extension Supracondylar Fractures

Pathophysiology. Extension supracondylar fractures occur as a consequence of a fall on the outstretched arm when the elbow is either fully extended or hyperextended (e.g., a fall off the

www.ketabpezeshki.com 66485457-66963820

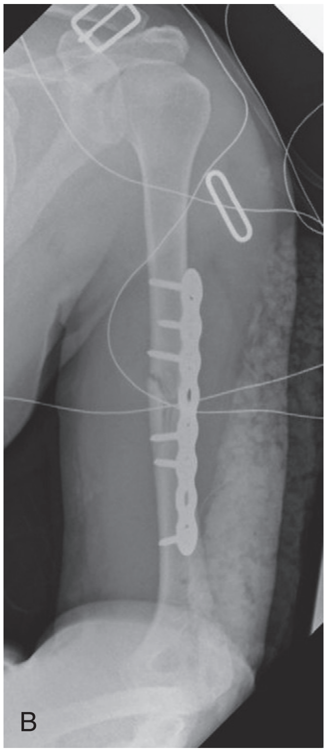

Figure 52-15. Midshaft humerus fracture: **A**, before and **B**, after open reduction and internal fixation.

“monkey bars”). The elbow is likely to be in the latter position at the time of the fall because ligamentous laxity, with hyperextension of the joints, is a normal phenomenon in younger children. With the forearm acting as a lever,[7] the ground reaction produces a moment of force at the elbow (Fig. 52-16). Ultimately the distal humerus fails anteriorly in the supracondylar area. The strong action of the triceps tends to pull and displace the distal fragment in a posterior and proximal direction. There may be anterior angulation of the sharp distal end of the proximal fragment into the antecubital fossa, endangering the brachial artery and median nerve (Fig. 52-17). In most cases, however, the brachialis muscle protects the anterior neurovascular structures from injury.

Clinical Features. A child with a complete fracture comes to the ED holding the upper extremity immobile in extension to the side, with a typical S-shaped configuration and tenderness and swelling in the region of the elbow. Prominence of the olecranon attached to the posteriorly displaced distal fragment is similar to that seen with posterior dislocation of the elbow. When an incomplete supracondylar fracture exists, the diagnosis may be less obvious, with an elbow effusion as the only clinical sign. A careful neurovascular examination is essential. Although palpation is useful in determining the site of injury, the examining physician should avoid manipulation of the injury to elicit crepitus because movement can cause further neurovascular damage. Alleviating pain often facilitates the examination.

Diagnostic Strategies. On radiographic examination, the distal fragment is often displaced on the lateral view. This displacement is most likely to occur with a complete fracture wherein the muscle activity results in proximal migration of the distal fragment. Because this fracture occurs in children, 25% of supracondylar fractures are of the greenstick variety, with the posterior cortex remaining intact. Subtle changes (e.g., the presence of a posterior fat pad or an abnormal anterior humeral line) may be the only radiographic clues to the presence of a fracture (Fig. 52-18). In displaced fractures on the anteroposterior view, the distal fragments may be displaced either medially or laterally in relationship to the humerus. Often, with minimally displaced fractures, the fracture line is transverse and not visible on the anteroposterior view. Based on radiographic findings, extension supracondylar fractures are classified into three types: type I, minimal or no displacement; type II, displaced fracture, posterior cortex intact; and type III, totally displaced fracture, anterior and posterior cortex disrupted.

Management. Nondisplaced fractures (type I) are immobilized primarily for comfort and protection because they are inherently stable. They are treated in a splint or cast flexed to 90 degrees with the forearm in neutral rotation. Protected active range of motion is begun in approximately 3 weeks. Even without definite radiographic findings, a child with localized tenderness consistent with a supracondylar fracture should be splinted and referred for follow-up examination within 24 to 48 hours. A radiographic study performed a few weeks after the injury may reveal periosteal new bone formation in the supracondylar region.

Minimally displaced (type II) fractures that are stable after reduction can be treated with splinting or casting with the elbow flexed. Some authors recommend flexion to 110 to 120 degrees for this injury.[6,8,9] This position uses the intact posterior periosteum as a tension band to hold the reduction; however, if swelling or circulatory obstruction prevents this much flexion, it cannot and should not be used. The greater the flexion at the elbow, the greater is the chance of vascular impairment. When swelling peaks at 24 to 48 hours, the risk of vascular obstruction and compartment syndrome is the greatest. Occasionally, these injuries must be pinned percutaneously to maintain stability, especially if a significant rotational component is present. Percutaneous pinning of fractures after reduction has grown in popularity in recent years.[10]

Type III totally displaced fractures generally are the result of more severe injuries that produce more swelling than type I or type II injuries. Displacement necessitates the reestablishment of length, increases the chance of varus deformity, and increases the chances of interposed soft tissues and neurovascular injury. For all these reasons, patients with type III fractures require immediate orthopedic consultation in the ED and should be admitted to the hospital for frequent neurovascular checks and closed versus open fixation and percutaneous pinning.

www.ketabpezeshki.com 66485457-66963820

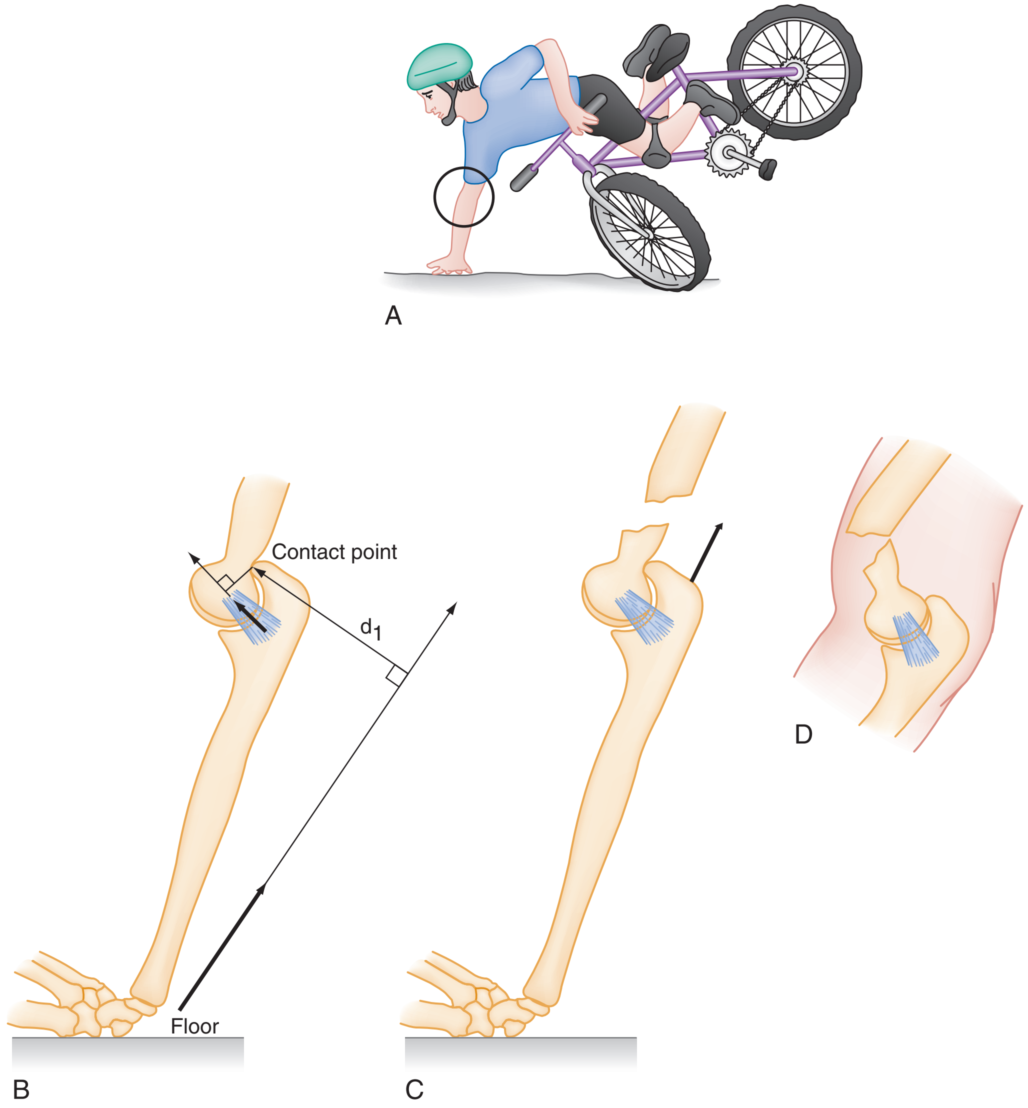

Figure 52-16. Mechanism of injury, extension supracondylar fractures. **A,** Fall on outstretched arm produces hyperextension of elbow. **B,** Ulna levers against distal humerus. **C,** Humerus fails, triceps exerts unopposed force. **D,** Distal fragment displaces.

These general principles should be adhered to in treating these injuries: (1) achieving adequate reduction, (2) properly assessing reduction, and (3) maintaining the reduction. Closed reduction is attempted with the patient under anesthesia. If closed reduction is not possible or if the brachial artery seems to be trapped in the fracture site, open reduction may be necessary. When adequate reduction has been achieved, most authorities recommend percutaneous pin fixation to maintain the reduction.[7,11,12]

Reduction in the ED is indicated only when the displaced fracture is associated with vascular compromise that threatens the viability of the extremity. Under these conditions, closed reduction should be attempted. After appropriate procedural sedation, an assistant fixes the arm of the patient. The physician grasps the patient's wrist and applies steady, firm traction in line with the long axis of the limb (Fig. 52-19A). The forearm is kept in the neutral, thumb-up position. While traction is maintained, correction of any medial or lateral displacement is accomplished with the other hand at the elbow (Fig. 52-19B). If the distal fragment is displaced laterally, it is pushed inward; if it is displaced medially, it is pushed outward.

After length has been restored and the angular deformity has been corrected, the thumb of the free hand is placed over the anterior surface of the proximal fragment with the fingers behind the olecranon. While traction is maintained, the elbow is gently flexed to just beyond 90 degrees (Fig. 52-19C). Angulation is corrected to a normal carrying angle.

Medially displaced supracondylar fractures are most prone to tilt into cubitus varus and are immobilized with the forearm pronated to tighten the brachioradialis and common extensor muscles. This procedure closes the fracture laterally. The less common laterally displaced fracture is immobilized in supination to close the fracture medially.

Only one attempt should be made at manipulation. Multiple attempts increase the likelihood of neurovascular injury and swelling. If reduction is unsuccessful, simple traction on the extended elbow may restore vascular supply. When reduction is performed, follow-up radiographs are obtained to ensure adequate reduction. Neurovascular function is checked at frequent intervals. Cylinder casts are not applied initially because they increase the risk of forearm ischemia; a posterior plaster splint provides safe and adequate immobilization.

Patients with type I fractures can be discharged safely from the ED with instructions to elevate the extremity, apply ice, and have a follow-up evaluation in 1 to 2 days. Fractures that require manipulation usually warrant admission to the hospital to ensure compliance and for neurovascular monitoring.

Figure 52-18. Supracondylar fracture *(arrow)* with anterior and posterior fat pads visible.

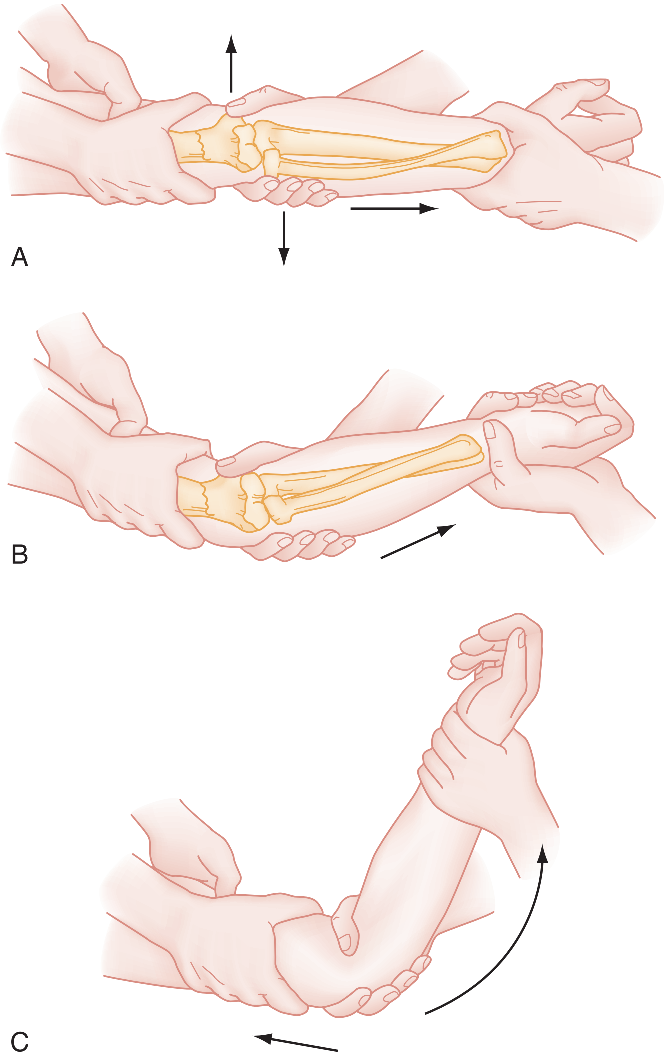

Figure 52-19. Steps in reduction of displaced supracondylar fracture (see text).

Complications. Ten percent of children lose the radial pulse temporarily, most often as a result of swelling and not direct brachial artery injury. Reducing the fracture, avoiding flexing the elbow more than 90 degrees, and elevating the arm help prevent secondary obstruction to arterial flow. Compartment syndrome, or Volkmann's ischemic contracture, as a result of prolonged ischemia of the forearm is a dreaded complication but is rare in this era (reported incidence <0.5%).[10]

The most common complication is the loss of the carrying angle, resulting in a cubitus varus, or "gunstock," deformity. Measurement of Baumann's angle after reduction is predictive of the final carrying angle. Cubitus varus has been reported previously in 25 to 60% of patients, depending on the treatment method used.[2,13] This incidence has decreased significantly (<10%) with the use of percutaneous pinning. The distal humerus has little capacity to remodel because only 20% of the growth of the bone derives from the distal physis. A small amount of extension or flexion deformity produces little disability, has the greatest chance of remodeling, and is not a major cosmetic concern. Valgus or varus deformities, being in the coronal plane, have little or no chance of remodeling. Although cubitus varus is not a significant functional disability, it presents a significant cosmetic problem. In most cases this complication can be corrected at a later time by an osteotomy.

Nerve injuries occurred in 7% of 4520 fractures compiled from 31 major reported series. The incidence increases to a range of 19 to 49% with increasing severity of fracture displacement.[14] The interosseous nerve is the most commonly injured, followed by the radial, median, and ulnar nerves. Most deficits seen at the time of injury are neurapraxias that resolve with conservative

www.ketabpezeshki.com 66485457-66963820

management. Motor function returns within 7 to 12 weeks, whereas recovery of sensation may take more than 6 months.[15]

Flexion Supracondylar Fractures

Pathophysiology. Flexion-type injuries are much less common, with a reported frequency of 1 to 10%, accounting for 2% of all supracondylar fractures in a large pooled series of patients.[16] The mechanism of injury is a direct blow to the flexed elbow. Energy is transferred from the posterior aspect of the proximal ulna to the distal humerus, resulting in a supracondylar fracture with anterior displacement of the distal fragment. As the fragment displaces, the periosteum is torn posteriorly.

Clinical and Radiographic Features. The elbow is usually held in flexion rather than with the extremity in the S-shaped configuration seen in extension-type injuries. In displaced fractures, the normal olecranon process is not palpable, in contrast to the increased prominence of the olecranon seen with extension injuries.

Radiographically, these injuries can be classified into three types, similar to extension injuries:

- Type I fracture—undisplaced or minimally displaced
- Type II fracture—incomplete fracture; anterior cortex intact
- Type III fracture—completely displaced; distal fragment migrates proximally and anteriorly

Plain films may reveal a simple increase in the anterior angulation of the distal supracondylar fragment or gross displacement of the distal fragment proximal and anterior to the distal end of the proximal fragment. In the latter case, the distal end of the proximal fragment protrudes posteriorly. A line down the anterior humeral shaft intersects the capitellum either normally or posteriorly in these fractures, depending on whether there is anterior displacement.[17]

Management. When the posterior periosteum is torn, the anterior periosteum functions as a tension band with the arm in extension. In type I fracture, the periosteum is minimally displaced. These injuries do not need to be immobilized in extension. The elbow can be comfortably flexed and should be immobilized in a splint as with extension injuries. Type II and III injuries should be referred to an orthopedist emergently. Type II injuries are manipulated into extension, then held either in a long arm cast or with percutaneous pins. Type III injuries often require open reduction (Fig. 52-20).

Complications. The most common complication is injury to the ulnar nerve by posterior displacement of the proximal fragment. The radial and median nerves are rarely injured. Stiffness of the elbow also may occur, especially after open reduction. Cubitus valgus may occur but is not as cosmetically problematic as cubitus varus.

Figure 52-20. Type III supracondylar fracture with significant displacement of distal fragment.

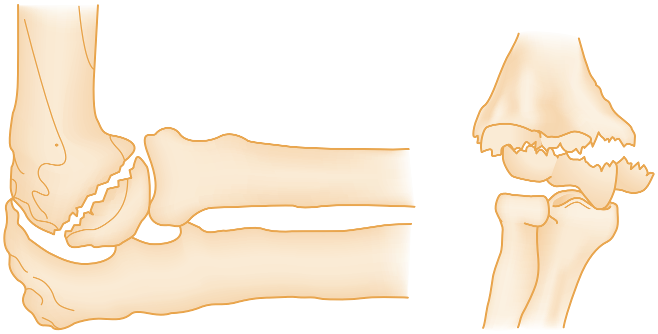

Figure 52-21. Transcondylar fracture of distal humerus. (*Left* from Ruiz E, Cicero J: Emergency Management of Skeletal Injuries. St Louis, Mosby, 1995. *Right* adapted from Simon R, Koenigsknecht S: Emergency Orthopaedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

Transcondylar Fractures

Transcondylar (or dicondylar) fractures have a fracture line, either transverse or crescent shaped, that passes through both condyles within the joint capsule just proximal to the articular surface (Fig. 52-21). As with supracondylar fractures, two types have been described—extension and flexion—based on the position of the elbow when fractured. Extension types are the most common. The mechanism of injury is similar to that for supracondylar injuries. In contrast to supracondylar fractures, however, the injury is more common in elderly individuals with fragile, osteoporotic bone. These fractures generally are difficult to treat because the small distal fragment possesses little extra-articular bone, and only a small amount of bone contact is available for union.[17] During healing, excessive callus may form in the olecranon or coronoid fossae with residual loss of motion. Orthopedic consultation should be immediately obtained for these injuries.

Intercondylar Fractures

Intercondylar fractures are usually T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment (Fig. 52-22). The distal portion of the fracture extends to the articular surface of the distal humerus. These injuries are rare and generally are seen in adults in their 50s and 60s.[18] The usual mechanism of injury is direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end.

Clinical and Radiographic Features. Patients with intercondylar fractures complain of pain at the elbow, which on examination is tender to palpation. Good-quality anteroposterior and lateral radiographic views are essential in evaluating fracture displacement and comminution (Fig. 52-23). Computed tomography may be used to delineate fracture patterns further. Neurovascular complications are not common with these injuries.

www.ketabpezeshki.com 66485457-66963820

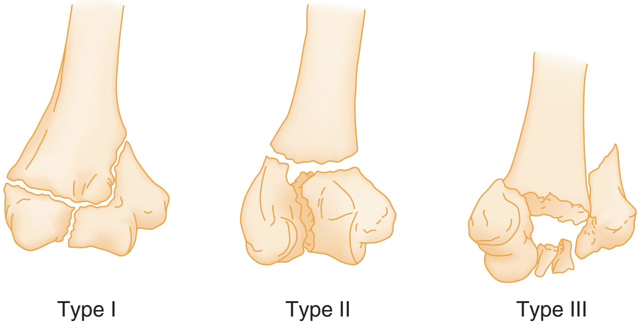

Figure 52-22. Intercondylar T fractures, types I, II, and III. (From Connolly JF: DePalma's Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1981.)

Management. Treatment of intercondylar fractures is difficult and complicated.[16,19] The goal of treatment is to reestablish articular congruity and alignment and to begin active motion as soon as possible, most often through open reduction with rigid internal fixation. Closed treatment is typically restricted to elderly patients, patients with medical conditions that prohibit surgery, and certain patients with nondisplaced fractures. These injuries all should be referred to an orthopedic surgeon emergently. As with supracondylar fractures, manipulation should be avoided unless limb-threatening ischemia is present. Traction across the elbow with the arm extended is helpful in restoring blood flow to an ischemic forearm.

Complications. Historically, loss of elbow joint function is the most common complication reported, although this now can be largely avoided with optimal surgical technique.[16] Any method of treatment that requires prolonged immobilization is likely to result in fibrosis or ankylosis of the joint. Neurovascular complications are rare.

Lateral Condyle Fractures in Children

Lateral condyle fractures are the second most common fractures involving the elbow in children, after supracondylar fractures.[20] The fracture has an age distribution similar to that of supracondylar fracture and occurs after a fall on the outstretched hand, with a varus stress applied to the extended arm.

Clinical and Radiographic Features. Tenderness and swelling are noted over the lateral aspect of the elbow. In general, children exhibit less swelling than with supracondylar fractures, and neurovascular compromise is uncommon. Diagnosis is usually made on standard anteroposterior and lateral views, although an oblique view also may be helpful. These fractures are notoriously difficult to diagnose because fractures with minimal displacement are difficult to see radiographically and are often misdiagnosed as supracondylar humerus fractures.

Management. Nondisplaced fractures are treated nonoperatively with a cast, whereas fractures with any displacement require closed or open reduction with percutaneous pin fixation for 3 to 4 weeks.[20,21]

Complications. The risk of neurovascular compromise is much lower than with supracondylar humerus fractures. Fractures diagnosed and treated in a timely manner should have few complications, although historically, nonunion, cubitus varus or valgus, and fishtail deformity (avascular necrosis) have been reported.[22]

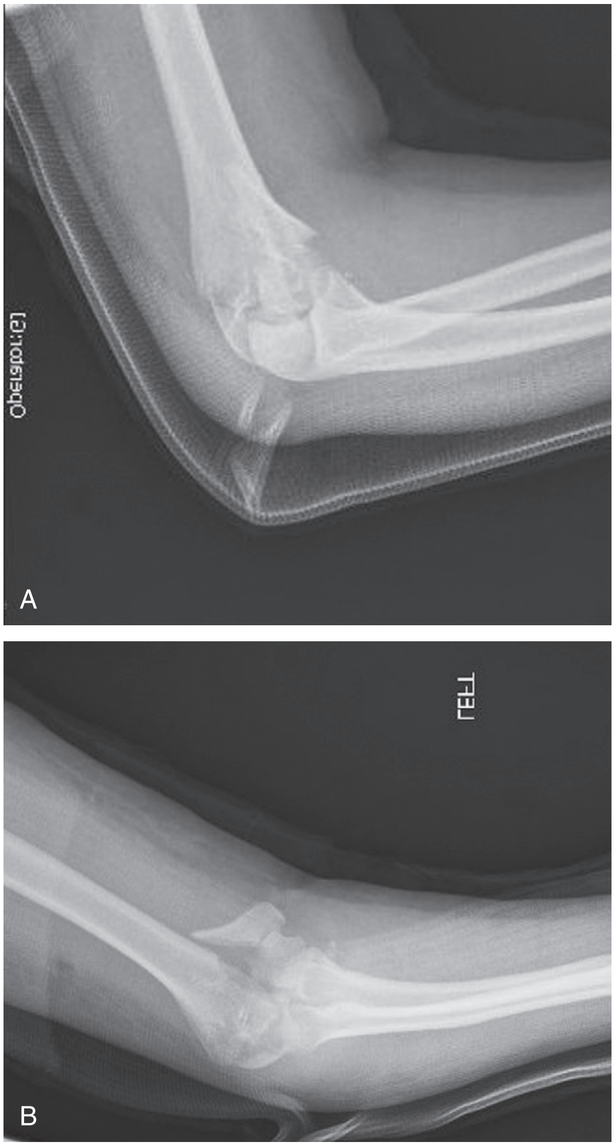

Figure 52-23. Intercondylar fracture, type III. **A,** Lateral and **B,** anteroposterior views.

Medial Condyle Fractures in Children

Medial condyle fractures are rare, comprising 1 to 2% of pediatric elbow fractures.[23] These fractures are type IV Salter-Harris injuries with physeal injury a possible outcome. The mechanism of injury is believed to be a valgus force on the extended elbow.

Clinical and Radiographic Features. The patient has tenderness and swelling over the medial aspect of the elbow. Anteroposterior, lateral, and oblique films may show the fracture in older children, but because the trochlea does not ossify until about age 9, plain films in younger children do not show the fracture. Magnetic resonance imaging (MRI) may be necessary to confirm the diagnosis in these patients.

Management. Operative treatment is indicated if displacement is greater than 2 mm; otherwise, conservative treatment is sufficient.

Complications. A study of 21 patients with medial condyle fractures revealed a 33% complication rate.[23] Complications included loss of reduction requiring reoperation, avascular necrosis, nonunion, and cubitus varus. Most minimally displaced fractures healed uneventfully.

www.ketabpezeshki.com 66485457-66963820

Condylar Fractures in Adults

Condylar fractures are rare in adults and typically involve the articular surface and the nonarticular portion of the distal humerus, including the epicondyle (Fig. 52-24). The status of the lateral trochlear ridge is the key to analyzing humeral condyle fractures. It may be involved with either medial or lateral condylar fractures and, when incorporated into the distal fragment, is far more likely to result in instability.

Pathophysiology. Lateral condylar fractures are uncommon, although more common than fractures of the medial condyle. The mechanism of injury is either a direct blow to the lateral aspect of the flexed elbow or a force that results in adduction and hyperextension with avulsion of the lateral condyle. Medial condylar fractures are rare and result from either a direct blow to the apex of the flexed elbow or a fall on the outstretched arm with the elbow forced into varus.

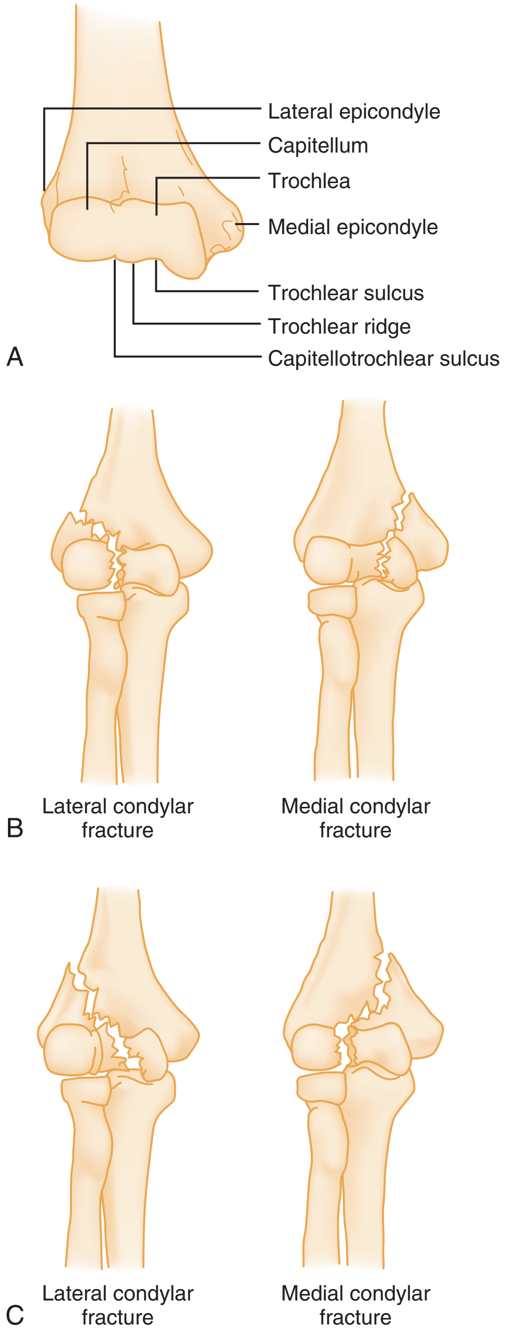

Figure 52-24. Condylar fractures. **A,** Normal anatomy. **B,** Lateral trochlear ridge not in fracture fragment (stable). **C,** Lateral trochlear ridge included with fracture fragment (unstable). (Adapted from Simon R, Koenigsknecht S: Emergency Orthopaedics: The Extremities, 2nd ed. Norwalk: Conn, Appleton & Lange; 1987.)

Clinical and Radiographic Features. The presentation of condylar fractures is similar to that of other distal humerus fractures, with swelling, tenderness, and crepitus localized over either the medial or the lateral elbow. On palpation, independent motion of the involved condyle may be appreciated. In lateral condylar fractures, findings may be accentuated with movement of the radius. On radiographic examination, lateral condylar fractures show a widening of the intercondylar distance. The distal fragment is often displaced, most commonly posteriorly and inferiorly. Because of the location of the ulnar nerve, it is imperative to test its function when this fracture is present. Medial condylar fractures are associated with tenderness over the medial condyle and pain with flexion of the wrist against resistance. On radiographic examination, displaced distal fragments tend to be anterior and inferior because of the pull of the forearm flexors.

Management. Immediate treatment depends on radiographic findings. For undisplaced or minimally displaced condylar fractures, immobilization of the flexed elbow in a long arm posterior plaster splint is sufficient. For lateral condylar fractures, the forearm should be supinated and the wrist extended to relieve the tension on the extensor muscle attachments. For medial condylar fractures, the reverse is true (i.e., the forearm should be pronated and the wrist flexed). For fractures displaced more than 3 mm, surgical fixation is required.

Complications. Complications include nonunion, restricted range of motion, joint instability, cubitus valgus or varus deformity, arthritis, and ulnar neuropathy. Because of the high rate of complications, orthopedic consultation should be sought for all condylar fractures.

Articular Surface Fractures

Capitellum Fractures

Pathophysiology. Fractures of the capitellum and trochlea typically occur together, usually as a result of posterior dislocation of the elbow, with isolated fractures being rarer. Injury to the capitellum occurs when the patient falls on an outstretched hand, jamming the radial head upward, similar to the motion of a piston, shearing off the capitellum into the radial fossa. Because the capitellum has no muscular attachments, the fragment may remain nondisplaced. More often the fragment is displaced (usually anteriorly, but occasionally posteriorly). Because of this mechanism, a radial head fracture also may be present and should be clinically suspected.

Clinical and Radiographic Features. The development of significant signs and symptoms may be delayed with capitellum fractures. Eventually, swelling within the capsule results in severe pain that manifests as well-localized tenderness on examination. Flexion of the elbow increases pain. A true lateral plain film usually shows the fragment lying anterior and proximal to the main portion of the capitellum (Fig. 52-25).

Management. Treatment begins in the ED with a posterior splint, ice packs, elevation, compression, and analgesia. Accurate anatomic alignment, rigid internal fixation, and early mobilization are prerequisites for a good functional result.[24] Fractures of the articular surfaces can be treated nonsurgically only if radiographs show perfect anatomic alignment.

Complications. Complications include post-traumatic arthritis, avascular necrosis of the fracture fragment, and restricted range of motion.

www.ketabpezeshki.com 66485457-66963820

Figure 52-25. Fracture of the capitellum.

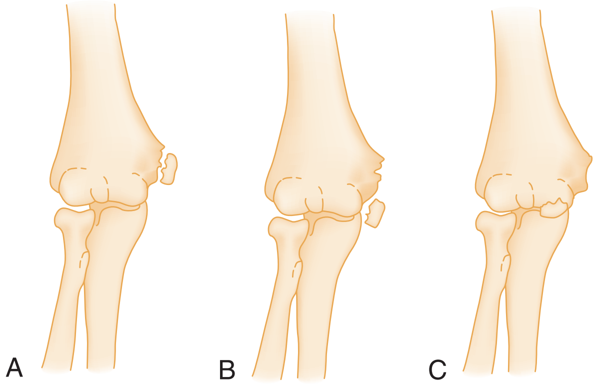

Figure 52-26. Fractures of medial epicondyle. **A,** Minimal displacement. **B,** Marked displacement. **C,** Displacement into joint. (From Connolly JF: DePalma's Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1981.)

Trochlea Fractures

Pathophysiology. Isolated fractures of the trochlea are exceedingly rare because of the structure's protected position deep within the elbow joint. The shearing force of the ulna against the trochlea is associated more commonly with posterior elbow dislocation.

Clinical Features. The elbow is painful, with an effusion and limited range of motion because this is an intra-articular injury. On the radiograph a fragment is visible lying on the medial side of the joint, just distal to the medial epicondyle, and signs of joint effusion are visible. The fracture may extend into the distal portion of the medial epicondyle.

Management. Nondisplaced fractures may be treated with a posterior splint for 3 weeks, followed by early range-of-motion exercises. Displaced fractures should be treated operatively; fragments that can be internally fixed are repaired, whereas small fragments are excised. Immobilization should be minimized to 10 to 14 days.[25]

Epicondyle Fractures

Most epicondylar fractures involve the medial epicondyle. Medial epicondyle fractures are most common in children and adolescents and often involve the apophysis, which is the last ossification center to fuse in the distal humerus, usually after age 15. Fractures through this ossification center usually occur in adolescence and constitute 11% of pediatric elbow fractures.[26] These are not Salter-Harris injuries because the apophysis is involved rather than the physis. Because the lateral epicondyle is almost level with the flattened outer surface of the lateral condyle, it has only minimal exposure to a direct blow, and fracture is extremely rare.

Pathophysiology. Medial epicondyle injuries occur from a variety of mechanisms. First, avulsion fractures are associated with posterior elbow dislocations in patients younger than 20 years in 30 to 55% of cases.[27] Second, repetitive valgus stress (as with throwing a ball) results in eventual avulsion fracture of the epicondyle (Little Leaguer's elbow). Another reported cause of fracture separation of the medial epicondyle, usually in adolescent boys, is arm wrestling.[28] Violent muscular forces associated with a shifting center of gravity during this activity seem to produce an avulsion just before closure of the epiphyseal plate. Finally, a direct blow to the medial epicondyle can cause this injury.

Clinical and Radiographic Features. The elbow is held in flexion, and any movement is resisted. Isolated fractures are associated with focal tenderness over the medial epicondyle. Use of the forearm flexors increases pain because their attachment is along the medial epicondyle. Ulnar nerve function should be evaluated. When the fracture is associated with a posterior dislocation, the examination reveals a prominent olecranon.

Simple fractures of the medial epicondyle are extra-articular injuries with limited soft tissue injury.[20] They generally do not produce a fat pad sign on the lateral radiographic view of the elbow. A posterior fat pad or significant swelling of the joint should suggest concurrent injuries, such as elbow dislocation. Careful radiographic evaluation is especially important because fracture fragments may migrate into the joint space. If the fragment is overlying the joint line on radiographic examination, it should be considered intra-articular (Fig. 52-26). Radiographic detection of the intra-articular fragment is often difficult.[27] Associated ulnar nerve palsy may be present with an entrapped fragment. Fragments may be difficult to see on radiographs, and a true anteroposterior view is difficult to obtain because of severe pain on extension. In an adolescent patient, there is a tendency to confuse the normal radiolucent epiphyseal growth plate with a fracture. In addition, minimally displaced fractures may be difficult to appreciate with radiographs. Comparison films of the uninjured elbow may be necessary. If dislocation is present, repeat radiographs taken after reduction should be evaluated for fragment location.

Management. If the fracture fragment is minimally displaced (<5 mm), treatment with a posterior splint is appropriate. To minimize distraction of the fragment by the forearm flexors, the elbow and wrist are flexed with the forearm pronated.

Treatment of displaced fractures is controversial. In the past, the amount of displacement often dictated the need for surgery. Results of operative and nonoperative treatment seem to be good, however, regardless of the degree of displacement.[29] Some experts advocate surgery for patients who participate in high-performance athletic activities that involve the injured extremity, but controlled studies are lacking.[20] Intra-articular fragments that cannot be removed from the joint by manipulation are an indication for surgery.[29] Immediate orthopedic consultation should be sought for these injuries. The rare lateral epicondylar fracture in adults was previously treated with immobilization, but more recent experience indicates that operative management is more successful.[30]

Little Leaguer's Elbow

Little Leaguer's elbow warrants special mention. An adolescent pitcher traumatizes immature epiphyses by repetitive throwing. Throwing the curve ball or breaking ball was previously implicated as a particular culprit, although the most important factor appears to be the total number of pitches per game.[31] It has been shown in a group of highly competitive young baseball players that this injury is also common in catchers and fielders.[32] The adolescent bone structure cannot withstand the extreme loading produced by repetitive hard throwing. Avulsion of the medial epicondyle or compression fracture of the subchondral bone of the lateral condyle or radial head may result (Fig. 52-27). This diagnosis should be sought in an athletic adolescent with medial epicondyle or radial head pain in the absence of acute injury by history. Adolescents with this condition should be forced to rest the elbow if throwing causes pain. After healing occurs, the amount of throwing and technique should be monitored carefully. The Committee on Sports Medicine and Fitness of the American Academy of Pediatrics and Little League Baseball recommend preventive measures to avoid these injuries, with guidelines for both pitch counts per game and mandated rest periods (Tables 52-2 and 52-3). The latest updates on new rules set forth by Little League Baseball can be found at www.littleleague.org.

Olecranon Fractures

Pathophysiology. Fractures of the olecranon may result from one of several mechanisms. Most commonly, a direct blow as a result of a fall, a motor vehicle or motorcycle crash, or an assault produces this injury. Such injuries are frequently comminuted. Less commonly, indirect force applied by forceful contraction of the triceps while the elbow is flexed during a fall can cause a transverse or oblique fracture through the olecranon. A combination of direct and indirect forces is believed also to cause some of these fractures. Olecranon fractures occur in adults and less commonly in children. The anatomic integrity of the olecranon is essential for triceps strength and normal function of the elbow, similar to the way intact patellar function is necessary for extension of the knee.

Clinical Features. Physical findings may include tenderness and pain over the olecranon, a palpable separation at the fracture site, or the inability to extend the elbow against force. This last finding indicates complete discontinuity of the pulling mechanism and the consequent failure of triceps function. The neurovascular status should be examined, with special attention given to the ulnar nerve distribution, because this structure is most vulnerable to injury in this location. Loss of sensation over the palmar aspect of the fifth digit and hypothenar eminence or motor weakness in the interossei muscles of the hand suggests ulnar nerve injury.

Diagnostic Strategies. Lateral radiographic views are most helpful. In addition to the fracture, the degree of comminution, the extent of articular surface disruption, and the amount of displacement in the 90-degree flexion position should be noted. Nondisplacement in this position indicates that the triceps aponeurosis is intact, and prolonged immobilization is unnecessary. Displacement of more than 2 mm is considered an indication for surgery (Fig. 52-28A). A fracture line that increases in separation with flexion of the elbow also is considered a displaced fracture. When this fracture is associated with elbow dislocation, the plane of instability is located through the fracture site and the radiohumeral joint, resulting in posterior displacement of the proximal fragment of the ulna and anterior dislocation of the radius and ulna as a unit (Fig. 52-28B).

Management. Undisplaced fractures can be treated conservatively on an outpatient basis with ice, compression, immobilization in 45 to 90 degrees of flexion, and analgesia. Follow-up films should be done at frequent intervals to ensure that subsequent displacement does not occur. Range-of-motion exercises can be started within 3 weeks in many cases.

Displaced fractures or fracture-dislocations require open reduction and internal fixation, and patients should be referred immediately to an orthopedic consultant. Displaced fractures in elderly patients sometimes are treated conservatively, but this should be left to the discretion of the consultant. Orthopedic referral also is necessary when ulnar nerve symptoms are present. These symptoms occur in 10% of patients, and in most cases the injury is an ulnar contusion that resolves spontaneously. The long-term outcome of treated olecranon fractures in adults is usually favorable with a low incidence of subsequent arthritis.[32]

Radial Head and Neck Fractures

Pathophysiology. Radial head and neck fractures, in general, are produced by an indirect mechanism, typically a fall on an outstretched hand. The radius transmits the force upward, driving the

www.ketabpezeshki.com 66485457-66963820

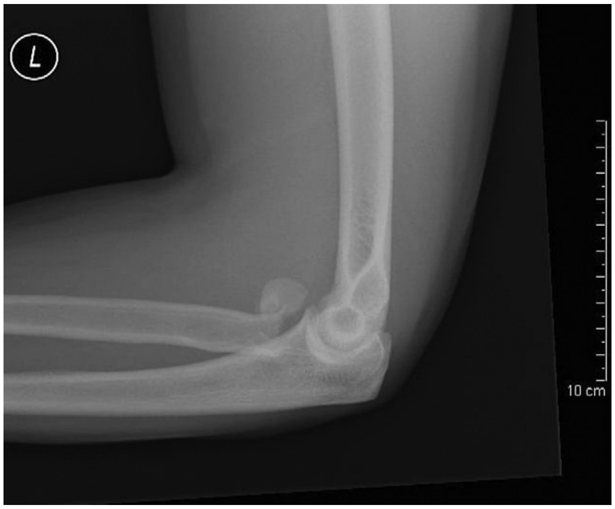

Figure 52-29. Radial head fracture with displacement.

radial head against the capitellum and resulting in fracture of the weaker radial head or neck. Although the fracture of the radial head may be the only radiographic finding, damage to the articular surface of the capitellum and injury to the collateral ligament commonly occur. Displacement of the radial head fragment suggests considerable force and significant soft tissue injury. This injury is characterized by localized tenderness over the radial head or pain with passive rotation of the forearm.

Diagnostic Strategies. Radiographic findings range from a subtle disruption of the usual gradual sweep of the radial neck and head surface to an obvious displaced or comminuted fracture (Fig. 52-29). Undisplaced fractures are notoriously difficult to see on radiographs. Tenderness coupled with a positive fat pad sign on the radiograph indicate that the injury should be treated as a radial head fracture even in the absence of a visible fracture. Radial head fractures are classified into four types:

- Type I—undisplaced fractures
- Type II—marginal fractures (involving <30% of the articular surface) with more than 2 mm displacement, including impaction or angulation
- Type III—comminuted fractures of the entire radial head
- Type IV—any of the previous types with elbow dislocation[33]

Management. Type I nondisplaced fractures are treated symptomatically with a brief period of sling support and early range-of-motion exercises (within 24-48 hours). Aspiration of the hemarthrosis and injection of 0.5% bupivacaine into the joint space may give dramatic relief of pain and improve the range of motion.[35] However, a recent prospective randomized study found no benefit to bupivacaine instillation compared with simple aspiration.[1] Most patients with this injury recover well in 2 to 3 months. A few do poorly, however, with long-term pain, contracture, or inflammation.

Type II injuries usually are treated similarly, with aspiration, instillation of bupivacaine, and immobilization in the ED, followed by a trial period of range-of-motion exercises. In these cases, aspiration of the joint and instillation of bupivacaine not only relieve pain but also allow testing of the range of motion to identify entrapped fragments. Radial head excision sometimes is performed later if the patient fails to improve. Early excision is advised for type II fractures when a mechanical block is present and for most type III fractures. Long-term functional results after radial head excision are acceptable in most patients, although a few have some functional disability after this procedure.[34] Type IV injuries are treated for the elbow dislocation as described next and for the specific radial head lesion.

DISLOCATION AND SUBLUXATION

Elbow Dislocation

Because of its anatomic structure, the elbow is inherently subject to mechanical instability, and dislocations are common. The elbow is second only to the shoulder as the most commonly dislocated large joint. *Elbow dislocation* is a term usually used to describe a disruption of the relationship between the humerus and the olecranon. In general, the radius and ulna, bound together firmly by the annular ligament and interosseous membrane, displace as a unit. Most classifications refer to the abnormal position of the ulna relative to the humerus. The elbow most often dislocates posteriorly, although it may dislocate anteriorly, medially, or laterally (Fig. 52-30). A dislocation also may occur between the radius and ulna, and such dislocations rarely occur concurrently with the ulnohumeral type. The latter are termed *divergent* dislocations.

Dislocation of the elbow requires considerable energy, and it is not surprising that a significant number of dislocations are associated with fractures of adjacent bony structures. A

www.ketabpezeshki.com 66485457-66963820

Figure 52-30. Elbow dislocation, posterior and anterior. (Adapted from Simon R, Koenigsknecht S: Emergency Orthopaedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

fracture-dislocation injury is referred to as a *complex elbow dislocation.* Immediate reduction of these dislocations is imperative to relieve pain and to prevent circulatory embarrassment or cartilaginous damage.

Posterior Elbow Dislocation

Pathophysiology. The mechanism of injury is a fall on the outstretched hand or wrist, the elbow being either extended or hyperextended at the time of impact. A valgus stress usually also occurs. The resultant forces lever the ulna from the trochlea and produce the dislocation.

Clinical and Radiographic Features. Patients hold the elbow in flexion at approximately 45 degrees and have marked prominence of the olecranon. Some elbow dislocations reduce before examination in the ED, presenting a confusing picture. In any case, significant diffuse tenderness and swelling are present. Neurovascular status is checked because brachial artery and median nerve injuries have been described. Neurovascular injury may occur from numerous mechanisms, including the initial traction, local swelling, and entrapment during reduction. Repeat examinations are mandatory.

A radiographic example of elbow dislocation before reduction is provided in Figure 52-31. Radiographic evaluation is crucial before manipulation to rule out fractures that can mimic dislocation on examination. Also, several fractures commonly occur in conjunction with dislocation, and these need to be identified and treated when present. These include fractures of the distal humerus, radial head, and coronoid process.

Management. Orthopedic consultation is usually not necessary to proceed. Reduction should be attempted immediately, especially if there is neurovascular compromise. Intra-articular injection of local anesthetic may provide adequate analgesia to allow for closed reduction. Procedural sedation is very helpful and often required to facilitate reduction. Rarely is a regional block or general anesthesia needed. Posterior dislocations are reduced with an assistant immobilizing the humerus and applying countertraction while traction is applied to the distal forearm. The ideal position is for the elbow to be flexed at 30 degrees with the forearm supinated while distal traction is applied. When the capitellum slides over the coronoid process, a coupling sound occurs as the articular surfaces mesh. If reduction is unsuccessful with this technique, the physician should apply downward pressure at the proximal forearm and apply pressure behind the olecranon while maintaining in-line traction. This downward force may help "unlock" the coronoid process, which may be trapped in the olecranon fossa. The joint is gently moved through its normal range of motion to check stability. If stable, the elbow is flexed to approximately 90 degrees and immobilized with a posterior plaster mold. The neurovascular status should be rechecked. Postreduction radiographs are important to avoid missing concomitant fractures of the coronoid process or radial head or, in children, separation of the medial epicondylar apophysis.

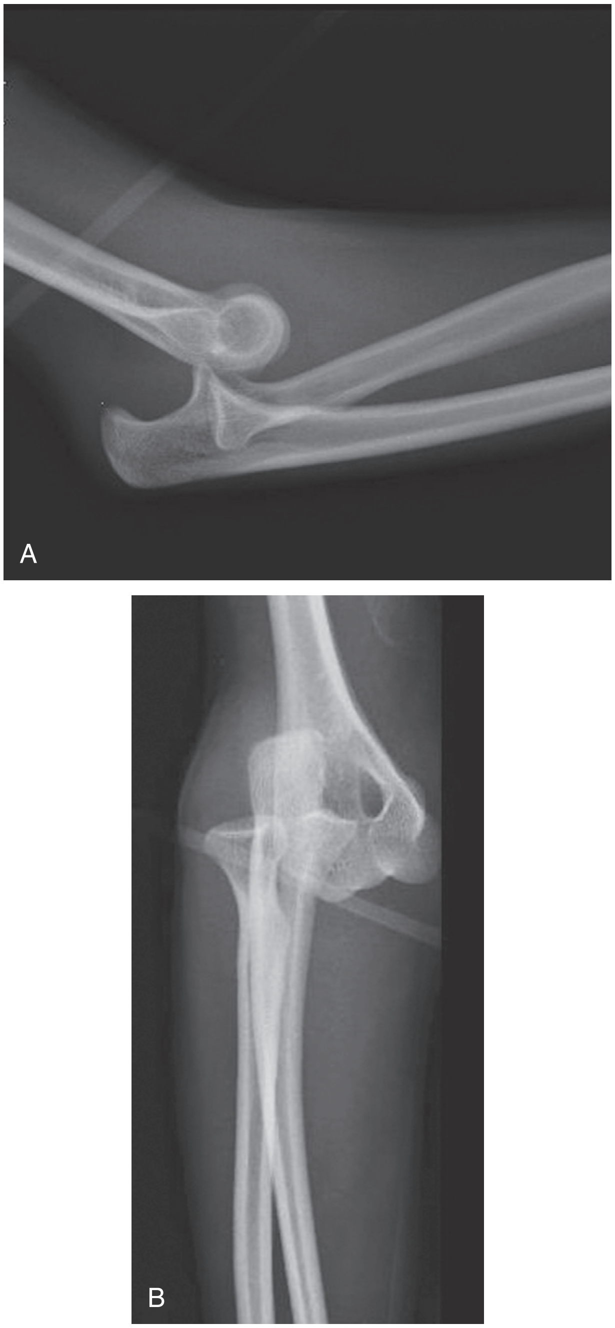

Figure 52-31. Characteristic posterior dislocation of elbow, lateral **(A)** and anteroposterior **(B)** views.

Postreduction management includes immobilization in a posterior splint with the elbow in as much flexion as circulation allows. The arm is suspended in a sling. Circular casting should be avoided initially. Patients can be discharged with instructions to apply ice, elevate, and watch for signs of vascular impairment. Patients should not be discharged until and unless they can follow such instructions. If the elbow is stable after reduction, gentle range-of-motion exercises may be initiated in 3 to 5 days. Unstable joints may require either prolonged immobilization in

www.ketabpezeshki.com 66485457-66963820

the presence of ligamentous instability or internal fixation for instability associated with fracture.[36]

Complications. The most serious complication of elbow dislocation is vascular compromise. Severe disruption results in injury to the brachial artery in 5 to 13% of cases.[37] Vascular injury should be sought when a wide opening between the tip of the olecranon and the distal humerus is palpated or seen on a radiograph. The presence of distal pulses is not proof of an intact artery, and if a question of vascular compromise exists, emergent vascular studies or consultation is indicated. Median nerve traction injuries and entrapment also have been reported. Loss of median nerve function after reduction should prompt immediate orthopedic consultation. Recurrent dislocation of the elbow is rare.

Medial and Lateral Dislocations

Medial and lateral elbow dislocations are produced by a mechanism similar to that in posterior dislocations, with a vector of force displacing the ulna and radius as a unit either medially or laterally. The anteroposterior view is the key to determining these dislocations. Reduction is carried out with the arm in slight extension but otherwise is similar to that for posterior dislocation. Care should be taken not to convert these to posterior dislocations during reduction. Complications and aftercare are the same as for posterior dislocations.

Anterior Elbow Dislocation

Pathophysiology. Anterior dislocations are rare and occur as a result of a blow from behind to the olecranon while the elbow is in the flexed position. Severe associated soft tissue trauma is present, including avulsion of the triceps mechanism or vascular disruption. These dislocations are frequently open.

Clinical Features. The upper arm appears shortened and the forearm elongated. The elbow is fully extended, and the forearm is supinated. The olecranon fossa is palpable posteriorly.

Management. Reduction of closed injuries is performed with distal traction of the wrist and a backward pressure on the forearm while the distal humerus is grasped. A click usually indicates that reduction has been achieved. These injuries have a higher incidence of vascular impairment than the more common posterior dislocation, but ulnar nerve injuries are unusual.[38] Emergent orthopedic referral is advised and is mandatory for open injuries or when vascular disruption is suggested.

Radial Head Subluxation

Pathophysiology

Subluxation of the radial head is a common injury, representing more than 20% of upper extremity injuries in children. Children aged 1 to 4 years are most often affected, although cases have been reported in children 6 months to 15 years of age. Girls are affected more commonly than boys, and the left arm is more commonly affected than the right.[39] This injury is called *nursemaid's elbow* because it results from a sudden longitudinal pull on the forearm while the child's arm is in pronation. Stretching of the annular ligament allows fibers to slip between the capitellum and the head of the radius, resulting in an inability of the child to supinate the arm. By the age of 5, the annular ligament becomes thick and strong and thus is far less likely to tear or be displaced.

Clinical and Radiographic Features

The classic history, present approximately half of the time,[40] is that of the forearm being pulled while in pronation with the elbow extended. Other mechanisms include direct trauma to the elbow or a twisting motion of the arm. In children younger than 6 months, the mechanism of subluxation involves rolling over in bed, which may trap the involved forearm under the body with resulting longitudinal traction on the joint. Clinically, the arm is held in passive pronation, with slight flexion at the elbow. The child is unable or unwilling to move the arm. Resistance to supination and tenderness on direct palpation over the head of the radius are present. Swelling, ecchymosis, and deformity are absent. Examination should include inspection and palpation of the entire extremity, including the clavicle.

When the history is suggestive of radial head subluxation, radiographs are not necessary and are rarely positive. If there is swelling or deformity, if there is an uncharacteristic history, if the child does not resume use of the arm after reduction, or if there is a possibility of nonaccidental trauma, appropriate radiographic studies are recommended. If palpation of the forearm, wrist, or humerus away from the elbow elicits reproducible tenderness, radiographs should be taken to exclude other diagnoses.

Management

Reduction may be attempted in children with typical presentations and is safe even when the classic history is absent. Supination-flexion is the method most commonly used in the past. Reduction is achieved by supination of the forearm while slight pressure on the radial head is applied with the examiner's thumb. In one continuous motion, the elbow is supinated and flexed with gentle traction applied. A click often, but not always, is felt as the radial head reduces (Fig. 52-32). A second technique of reduction, hyperpronation, has a significantly higher reported success rate of reduction on the first attempt.[41] With the hyperpronation method, the child's elbow is supported with moderate pressure applied to the radial head. The examiner then grips the child's distal forearm and hyperpronates the forearm, resulting in a click felt over the radial head (Fig. 52-33).

Many patients are asymptomatic within 5 to 10 minutes; 90% of patients regain use of the arm within 30 minutes. Hearing or palpating a click is associated with success. It is a good idea for the physician to leave the room and for parents to distract the child to show return of normal function. A fearful child often does not use even the successfully reduced limb. If function does not return within 24 hours, the patient should be reevaluated. After successful reduction, no additional treatment, immobilization, or activity reduction is necessary. Parents and caregivers should be instructed to avoid excessive traction on the child's forearm to prevent recurrent radial head subluxation. The recurrent radial head subluxation rate is approximately 20%.[42] Most of these injuries are unintentional on the part of the caregiver, but inflicted injury should be considered in suggestive cases.

SOFT TISSUE DISORDERS

Epicondylitis (Tennis Elbow)

Pathophysiology

Tennis elbow is a term first introduced in the 1880s to describe an inflammatory process that involves the radiohumeral joint or lateral epicondyle of the humerus. It is a common exercise-related syndrome, and the mechanism is thought to be repetitive pronation and supination of the forearm. The actual pathologic nature of this syndrome is unclear. Radiohumeral bursitis or synovitis, tendinitis of the common extensor tendon, periostitis of the lateral epicondyle, and entrapment by scar tissue of the radial nerve all have been suggested as culprits in this syndrome. Histologically, the abnormality has been described as *angiofibroblastic*

www.ketabpezeshki.com 66485457-66963820

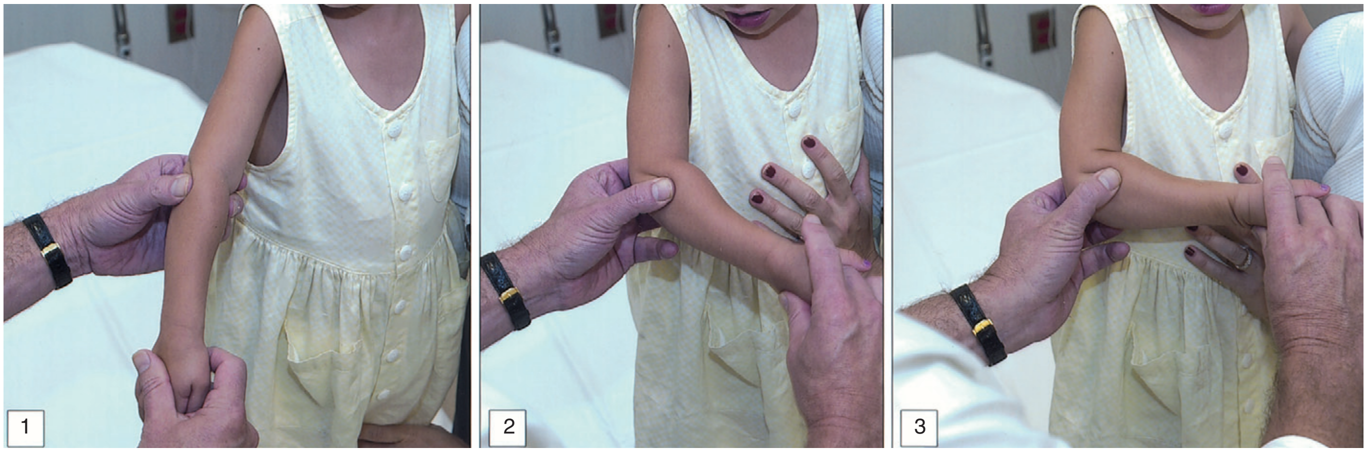

Figure 52-32. Subluxation of the radial head. Method of reduction: *(1)* Apply pressure to radial head, *(2)* supinate the forearm, and *(3)* flex elbow, in one continuous motion.

hyperplasia, a term subsequently modified to *angiofibroblastic tendinosis.* The cause has been theorized to be a degenerative process because of the paucity of acute inflammatory cells seen histologically.[43] Medial tennis elbow and posterior tennis elbow have been reported, the former involving the pronator teres and flexor carpi radialis insertions and the latter involving the triceps tendon. The following discussion pertains to lateral tennis elbow.

Clinical and Radiographic Features

Whatever the cause, the onset is usually gradual. Patients report dull pain over the lateral aspect of the elbow, increased by grasping or twisting motions. Tenderness is located over the lateral epicondyle or radiohumeral joint. Supination and pronation against resistance may be painful. Pain can be shown by stretching the wrist extensors. To test this, the elbow is extended, the forearm pronated, and the wrist fully dorsiflexed.

Radiographic findings may be normal, although with chronicity, calcifications may be present over the lateral epicondyle. Characteristic MRI findings also have been described, although MRI is not indicated emergently.

Management

Traditional treatment includes protection, rest, ice, compression, elevation, and medication. Initial therapy includes avoidance of the inciting activity and immobilization with a sling. Nonsteroidal anti-inflammatory drugs are often used, but their efficacy probably is limited to their analgesic rather than their anti-inflammatory properties. Injection of a corticosteroid at the point of tenderness provides some pain relief in most patients.[43,44] Because corticosteroids weaken collagen, premature resumption of heavy loading of the tendon at the lesion should be avoided, as should injection directly into the tendon. Patients with pain that persists despite treatment and a rehabilitation program should be referred for possible surgery.[45] Modification of athletic technique is recommended after the symptoms subside.

Olecranon Bursitis

Pathophysiology

Although several bursae are located in the elbow region, the olecranon bursa is the one most often involved in an isolated pathologic process. Olecranon bursitis commonly is caused by repetitive

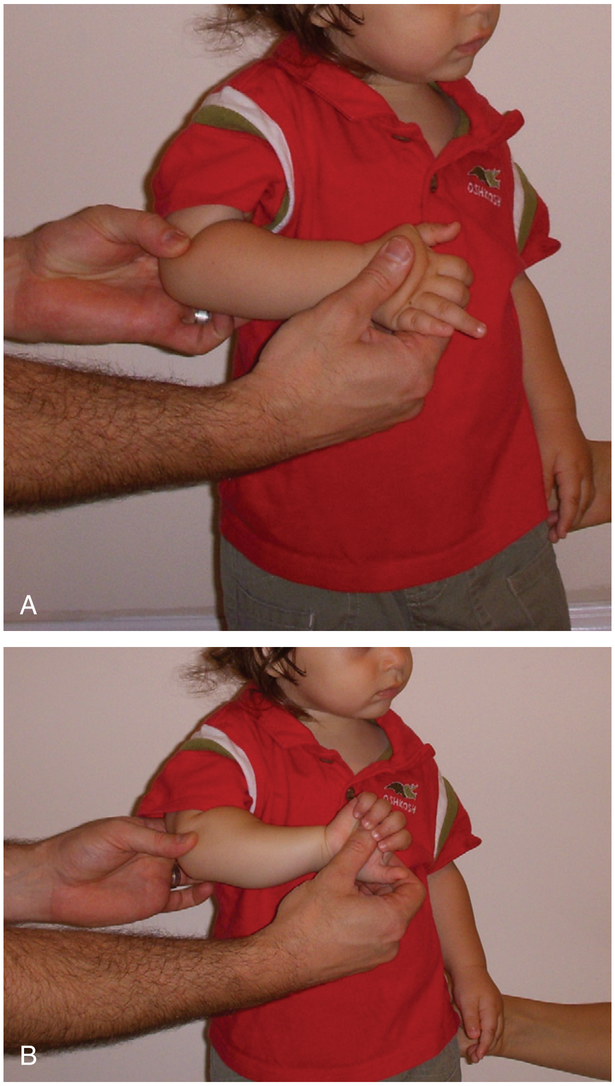

Figure 52-33. Hyperpronation method of radial head subluxation reduction: **A,** Support elbow with pressure to radial head, then hyperpronate the arm distally **(B)**.

www.ketabpezeshki.com 66485457-66963820

minor trauma, such as leaning on the elbow during work activities. It also may result from an inflammatory process, such as gout or an infectious process within the bursa (septic bursitis). Septic olecranon bursitis occurs most commonly in patients engaged in work that predisposes to repetitive trauma to the elbow, such as gardening or plumbing.

Clinical Features

Patients usually have progressive pain, tenderness, and swelling over the olecranon. Some patients with septic bursitis have an abrupt onset instead, with a rapid increase in pain over a few hours. On examination, the septic bursa is typically swollen, hot, erythematous, and tender. Flexion often is limited by pain brought on by tightening of the skin over the inflamed bursa. Minor breaks in the skin, frank abrasions, or healing lacerations over the bursa may be present. Noninfectious bursitis usually manifests with less warmth and erythema. The skin is intact, and swelling may be the only finding. The most important aspect of evaluation is the differentiation of a septic process from a benign inflammatory one. This differentiation may be difficult on clinical grounds because considerable overlap exists in the histories and physical findings.

Diagnostic Strategies

If doubt exists, aspiration of the bursa should be performed and the aspirate sent for crystals, white blood cell count, Gram's stain, and cultures. Unless the aspirate is frankly bloody, traumatic nonseptic olecranon bursitis usually has a leukocyte count lower than 1000 cells/mm^3, whereas septic bursal fluid usually has a count higher than 10,000 white blood cells/mm^3.

Management

Aspiration is diagnostic and therapeutic because relief of pressure relieves some of the pain. In cases of purulent bursitis, the bursa should be drained, and appropriate antibiotics should be begun in the ED. Pending culture results, empirical antibiotics should include coverage for routine skin organisms as well as methicillin-resistant *Staphylococcus aureus* (MRSA). Bursitis refractory to aspiration and appropriate antibiotics may require incision and drainage. Noninfectious bursitis can be managed with a compression dressing, ice, nonsteroidal anti-inflammatory medications, and avoidance of the inciting activity. Patients who have had their bursa aspirated should be rechecked within 24 to 48 hours to verify culture results and monitor their response to treatment.

Biceps Tendon Rupture

Pathophysiology

Biceps tendon rupture occurs most commonly in the proximal portion of the long head of the biceps. It is most common in middle-aged athletes or physical laborers who sustain repetitive microtrauma to the tendon. Patients experience a snapping sound and pain in the anterior shoulder during strenuous activities that produce rapid loading of the muscle. Rupture also occurs distally, usually as an avulsion from the insertion on the radial tuberosity, although ruptures at the musculotendinous junction occasionally occur. Rupture of the distal biceps tendon occurs almost exclusively in men, most commonly between the ages of 40 and 60, and most often involves the dominant arm.[46-47] The inciting event is usually an unexpected extension force applied to the arm flexed at 90 degrees. The pathophysiology of tendon rupture is poorly understood, although tendon rupture generally occurs in the setting of underlying tendinosis. Biceps tendon tears are becoming more common in players in the National Football League (NFL), most commonly in offensive linemen.[48] Diabetes, chronic renal failure, systemic lupus erythematosus, rheumatoid arthritis, and steroid or fluoroquinolone therapy all may result in tendinosis. Smoking has been shown to be strongly associated with distal biceps tendon rupture.[49]

Clinical Features

The diagnosis is usually obvious. In proximal tendon rupture, the patient usually has a visible defect at the top of the bicipital groove with bunching of the muscle distally. Flexing of the elbow produces pain at the proximal insertion. Flexion remains intact, however, because the short head of the biceps usually maintains its integrity. With distal ruptures the patient reports pain and tearing in the antecubital region. Visible deformity and a palpable defect of the biceps muscle belly are present with weakness of elbow flexion and supination. If the tendon is completely ruptured, there is a bunching up of the muscle, and this effect is accentuated when the patient attempts flexion. Radiographs are not revealing and usually not necessary. MRI may be useful when a partial rupture is suggested.

Management

All patients require urgent referral to an orthopedist. Early anatomic repair of complete ruptures usually is recommended. Partial ruptures occasionally respond to conservative treatment but also may require surgical repair. The arm should be splinted and the patient advised to apply ice and be given analgesics while awaiting orthopedic consultation.

KEY CONCEPTS

- Clinical decision rules for the elbow joint have not been validated. Radiographs should be obtained when there is limitation in range of motion, obvious deformity, joint effusion, or significant tenderness or crepitus over any of the bony prominences or the radial head. In the absence of these, it would seem appropriate to omit radiographs in adults. The threshold for imaging should be lower in pediatric patients owing to the presence of open growth plates and limitations to the physical examination.
- In children with wrist pain and traumatic mechanism of injury, the absence of a clear-cut explanation for the pain (e.g., no abnormal radiographic findings) should prompt consideration of an elbow injury causing referred pain to the wrist.
- In the setting of trauma, more than 90% of patients with the posterior fat pad sign of the elbow have intra-articular skeletal injury. In adults, a radial head fracture is implied, whereas in children, a supracondylar fracture is the probable underlying injury. In the absence of trauma, other causes of effusion (e.g., gout, infection, or bursitis) should be considered.
- The most common complication, radial nerve injury, occurs in 20% of humerus fractures. This is most often a benign neurapraxia that resolves spontaneously in most patients, although recovery may take several months. Radial nerve injuries associated with penetrating trauma or open fractures are likely to be permanent and usually warrant operative exploration.
- Generally the radius and ulna, bound together firmly by the annular ligament and interosseous membrane, displace as a unit and typically dislocate posteriorly, although anterior, medial, or lateral dislocations may occur.
- Radiographic studies are not required when the history suggests radial head dislocation (nursemaid's elbow). If there

www.ketabpezeshki.com 66485457-66963820

is swelling or deformity, if there is an uncharacteristic history, if the child does not resume use of the arm after reduction, or if there is a suggestion of child abuse, appropriate radiographic studies should be obtained.

- Biceps tendon rupture occurs almost exclusively in men, most commonly between ages 40 to 60, most often involving the dominant arm, and usually subsequent to an unexpected extension force applied to the arm flexed at 90 degrees. Smoking, diabetes, chronic renal failure, systemic lupus erythematosus, rheumatoid arthritis, and steroid or fluoroquinolone therapy may predispose to this injury. This injury is increasing in frequency in NFL players, usually in offensive linemen, and may become more common in college athletes as well.

ACKNOWLEDGMENT

We would like to thank Drs. Joel M. Geiderman and Sam S. Torbabi for their work on this chapter in previous editions.

Chapter 53

Shoulder

Mohamud R. Daya and Rachel R. Bengtzen

PERSPECTIVE

The shoulder joint is a unique and complex articulation unit. It has the largest range of motion of any appendicular joint in the body and can be moved through a space that exceeds a hemisphere in extent. The nature of shoulder injuries has been long recognized: Wall paintings in Egyptian tombs from 3000 BCE show accurate drawings of manipulations (similar to the Kocher technique) used to reduce shoulder dislocations.[1] Hippocrates outlined the oldest known method for reduction of shoulder dislocations.[2]

Shoulder injuries are commonly encountered in emergency medicine. Statistical studies show that 8 to 13% of all athletic injuries involve the shoulder and that shoulder dislocations account for more than 50% of all major joint dislocations seen in the emergency department (ED). Almost every major sport or athletic activity involves use of the shoulder joint in one way or another. The shoulder can be injured by trauma (indirect or direct) or by overuse. Traumatic injuries tend to occur in contact sports such as football and ice hockey, whereas overuse injuries (impingement syndromes) are more common in swimming and baseball. Shoulder injuries also are common in wrestling, tennis, volleyball, and javelin throwing.[3]

In general, children are vulnerable to the same injuries as those incurred by adults; however, the presence of the epiphysis and its growth plate changes the pattern of injuries.[4] The strength of the joint capsule and its ligaments is two to five times greater than that of the epiphyseal plate. An injury that produces a sprain or dislocation in an adult often causes a fracture through the hypertrophic zone of the growth plate in a child. The shoulder girdle has epiphyseal plates at the acromion process, proximal humeral head, coracoid process, glenoid cavity, and medial end of the clavicle. Complete or greenstick fractures of the clavicle and fractures of the proximal humeral epiphysis are encountered more commonly in the pediatric population. Most shoulder injuries in children can be treated conservatively, with a good prognosis for full return of function.[4]

PRINCIPLES OF DISEASE

Anatomy

The shoulder girdle connects the upper extremity to the axial skeleton (Fig. 53-1). It consists of three bones, the *clavicle, humerus,* and *scapula;* three joints, the *acromioclavicular, glenohumeral,* and *sternoclavicular* joints; and one pseudoarticulation, the *scapulothoracic* pseudoarticulation.

The sternoclavicular joint (SCJ) represents the only true articulation between the upper extremity and the axial skeleton (Fig. 53-2). Stabilizers of this diarthrodial joint include the anterior and posterior sternoclavicular ligaments, the interclavicular ligament, and the costoclavicular ligament. The costoclavicular ligament opposes the pull of the sternocleidomastoid and is considered the most important stabilizing ligament.[5] The SCJ participates in all movements of the upper extremity and is the most moved joint in the body. The superior mediastinum with its great vessels, trachea, esophagus, thoracic duct, lung apices, and other important structures is immediately posterior to the joint.

The clavicle is an S-shaped bone that acts as a strut to support the upper extremity and keep it away from the chest wall. It articulates medially with the sternum and laterally with the acromion process. The clavicle provides the neck with an acceptable cosmetic appearance and protects the subclavian vessels and brachial plexus. Its middle third, which is thin and untethered, is the most commonly fractured segment.[6]

The acromioclavicular joint (ACJ) connects the lateral end of the clavicle with the medial aspect of the acromion process (Fig. 53-3). The diarthrodial ACJ has little or no bony stability and is dependent on the associated ligaments and muscles for support.[7] The weak acromioclavicular ligaments provide posterior support while the clavicular and acromial attachments of the deltoid and trapezius muscles provide static and dynamic support for the superior aspect of the joint. The most important stabilizers are the coracoclavicular ligaments (conoid and trapezoid), which provide vertical and anterior support.

The scapula is a flat triangular bone that forms the posterior aspect of the shoulder girdle. The thin body of the scapula lies flat against the posterior thorax and widens laterally to form the glenoid fossa. The scapula's thickened borders are the attachment sites for 18 muscle origins and insertions.[8] The thick muscle coat and ability to recoil along the posterior chest wall protect the scapula from both direct and indirect trauma.

A synovial membrane extends from the glenoid fossa to the humeral head. The membrane is large and redundant inferiorly to accommodate the extensive range of movement. Overlying the synovial membrane is a loose and redundant fibrous capsule. Anteriorly, the capsule is thickened to form the superior, middle, and inferior glenohumeral ligaments. The anterior band of the inferior glenohumeral ligament is the most important restraint to anterior glenohumeral dislocations.[9]

The glenohumeral articulation is a ball-and-socket–type joint that depends largely on associated capsule, muscles, and ligaments for stability (Fig. 53-4). A negative intracapsular pressure completes the stabilization mechanism.[9,10] The absence of bony stability permits a range of motion, however, that is greater than that of any other joint in the body.

The proximal humerus articulates with the glenoid fossa and provides for the attachment of many important muscles. The

supraspinatus, infraspinatus, and teres minor insert onto facets of the greater tuberosity, whereas the subscapularis inserts onto the lesser tuberosity. Together, this group of muscles forms the rotator cuff, which helps stabilize the humeral head within the glenohumeral joint (Fig. 53-5). The long head of the biceps tendon originates from the supraglenoid tubercle and ascends over the humeral head to enter the arm via the bicipital groove. The long head acts as an additional stabilizer for the superior

and anterior aspects of the glenohumeral joint (see Fig. 53-5). Long muscles that cross the articulation are involved primarily in movements of the glenohumeral joint. The pectoralis major, latissimus dorsi, and teres major muscles all insert into the humeral intertubercular groove. Displacements encountered with fractures of the humerus usually reflect the pull of these attached muscle groups. The proximal humerus is composed primarily of trabecular bone with a thin cortical shell. Changes in bone density with age (osteoporosis) greatly increase the risk of fractures in this area.[6]

The brachial plexus and subclavian vessels enter the shoulder girdle complex superiorly between the clavicle and the first rib, traverse under the coracoid process, and exit anterior to the inferior aspect of the glenohumeral joint as the median, ulnar, and radial nerves and axillary vessels. These nerves represent the final branches of the upper brachial plexus (nerve roots C5 to C8), and injuries to the brachial plexus invariably result in significant shoulder dysfunction.

CLINICAL FEATURES

History

Most complaints usually involve some combination of pain, stiffness, instability, and weakness. Pain can result from many different conditions extrinsic and intrinsic to the shoulder. Extrinsic sources of shoulder pain include disorders of the cervical spine, thoracic outlet syndromes, and Pancoast tumors. In addition, pain can be referred to the shoulder from myocardial processes, diaphragmatic irritation (e.g., subphrenic abscess, lower lobe pneumonia, splenic hematoma, ruptured ectopic pregnancy, gallbladder disease), and gastric or pancreatic diseases.

Acute intrinsic pain usually is associated with a traumatic event. The most important factors to determine are the time and mechanism of injury, its precise location, the intensity of the pain, and associated sensorimotor complaints. Occasionally, the patient may have acute pain in the absence of associated trauma (e.g., with calcific tendinitis). Shoulder pain also can manifest in an insidious manner, unrelated to any precipitating factor. In these instances, the duration, location, character, and aggravating and alleviating factors of the pain should be noted. Intrinsic shoulder pain in general does not radiate past the elbow.

Stiffness usually signifies a restricted range of motion resulting from an underlying painful condition of the shoulder. Instability can be seen in the form of an obvious subluxation or dislocation. Alternatively, the patient may describe the sensation of the shoulder's almost "going out." A rotator cuff tear or an underlying nerve lesion usually causes significant shoulder weakness.

Physical Examination

The shoulder should be inspected from the anterior, posterior, and lateral positions. Any obvious deformity, ecchymosis, laceration, swelling, or hematoma should be noted. The masses of the trapezius, deltoid, infraspinatus, and supraspinatus muscles should be compared with the unaffected side to detect any atrophy.

Palpation of the shoulder should be performed systematically, beginning at the SCJ and moving laterally along the clavicle to the ACJ. Next, the scapula, glenohumeral joint, and humerus are palpated. Any point tenderness, crepitus, swelling, or deformity should be noted.

Active and passive ranges of motion should be tested. Active range of motion is best determined with the patient in the sitting position, which eliminates the contributions of the lumbar spine and lower extremity joints. Passive range of motion is best evaluated with the patient in the supine position. The degrees of abduction, forward flexion, extension, and internal and external rotation should be recorded and compared with those for the unaffected extremity. In addition, the motion of the scapulothoracic articulation should be observed carefully in all cases. After 45 degrees of abduction, the scapula moves approximately 1 degree for every 2 degrees of glenohumeral motion.

www.ketabpezeshki.com 66485457-66963820

The examination is completed with an assessment of the neurovascular function. A complete sensory (light touch and pinprick) and full motor examination of the brachial plexus should be performed. This examination is best performed by assessing the myotomes and dermatomes (Table 53-1) pertinent to each nerve root within the brachial plexus. The radial pulse should also be checked, although collateral circulation may preserve this in the presence of a vascular injury. The presence of pallor, paresthesias, or an expanding hematoma should raise suspicion for a vascular injury. The neurovascular examination should be repeated after any manipulation in the ED, and the findings recorded.

DIAGNOSTIC STRATEGIES

Radiology

The initial assessment of traumatic injuries includes a three-view series of radiographs consisting of true anteroposterior (AP) (45-degree lateral), transscapular lateral ("Y" view), and axillary lateral views (Figs. 53-6 and 53-7). The true AP view (see Fig. 53-7B) is preferred over standard AP views because it shows the glenohumeral joint without any bony overlap. Standard AP views taken with the joint in internal and external rotation profile the lesser and greater tuberosity and are more useful in the evaluation of soft tissue conditions.

Table 53-1 Sensory and Motor Components of the Brachial Plexus

SPINAL LEVEL	SENSORY AREA	MUSCLE
C2-4	—	Trapezius
C5	Lateral arm	Deltoid
C6	Lateral forearm and thumb	Biceps
C7	Tip of long finger	Thumb extensors
C8	Tip of little finger and medial forearm	Finger flexors
T1	Medial arm	Hand interossei

Acceptable orthogonal views include the axillary lateral, transscapular lateral, and apical oblique.[11] The preferred view is the axillary lateral (see Fig. 53-7A), which projects the glenohumeral joint in a cephalocaudal plane. This view is particularly useful for defining the relationship of the humeral head with the glenoid fossa and in identifying lesions of the coracoid process, humeral head, and glenoid rim. Some degree of abduction is required for the axillary view, and patient cooperation with this position may be limited by pain. The difficulty in obtaining this view has led to the popularity of the transscapular view (see Fig. 53-7B). Advantages of this projection include its simplicity and reproducibility and a clear delineation of anatomic structures. In this view the scapula is projected as a Y, with the body forming the lower limb and the coracoid and acromion processes forming the upper limbs. The humeral head normally is superimposed over the glenoid, which is located at the junction of the three limbs. This view is particularly useful in identifying anterior and posterior glenohumeral dislocations. The apical oblique view (obtained by having the patient stand bending forward, and angling the central ray 45 degrees caudally) shows the glenohumeral joint in a unique coronal projection. This view can be obtained easily and painlessly and has been found to be useful in evaluating for Hill-Sachs lesions in shoulder dislocations, and displacement and angulation of proximal humerus fractures.[11]

Plain radiographs are the mainstay of the radiologic examination in the ED, but in selected circumstances, additional bone and soft tissue details may be obtained via computed tomography (CT) or magnetic resonance imaging (MRI). Bedside ultrasonography is emerging as a reliable screening and diagnostic imaging modality for selected injuries, in particular fractures of the clavicle.[5,12]

SPECIFIC INJURIES

Fractures

Clavicle

Pathophysiology. The clavicle accounts for 5% of all fractures and is the most commonly fractured bone in children. Epidemiologic

studies in adults have documented an annual incidence rate of 29 to 64 per 100,000 population, with a 2:1 male-to-female ratio.[13] Clavicular fractures are classified anatomically and mechanistically into three groups. Fractures of the medial third are uncommon (5%) and occur as a result of a direct blow to the anterior chest. Fractures of the middle third are the most frequent (Fig. 53-8), accounting for 80% of all injuries. The usual mechanism of injury involves a direct force applied to the lateral aspect of the shoulder as a result of a fall, sporting injury, or motor vehicle collision (MVC). Fractures of the lateral third (15%) result from a direct blow to the top of the shoulder and are classified further into three subtypes.[13] Type I fractures are stable and minimally displaced because the coracoclavicular ligament remains intact. Type II fractures are associated with a torn coracoclavicular ligament and have a tendency to displace because the proximal fragment lacks any stabilizing forces. Type III injuries involve the articular surface (Fig. 53-9).

Clinical Features. The patient has pain over the fracture site, and the affected extremity is held close to the body. With fractures of the middle third, the shoulder typically is slumped downward, forward, and inward. This positioning is a result of the effect of gravity and the pull of the pectoralis major and latissimus dorsi on the distal fragment. The proximal fragment often is displaced upward by the action of the sternocleidomastoid. The head is often tilted toward the injured side in an attempt to relax the effects of these displacing muscular forces. Ecchymosis, crepitus, and a palpable or visible deformity may be noted over the fracture site.

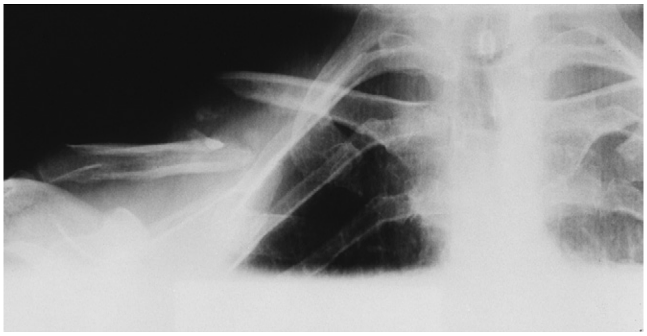

Figure 53-8. Displaced midclavicular fracture.

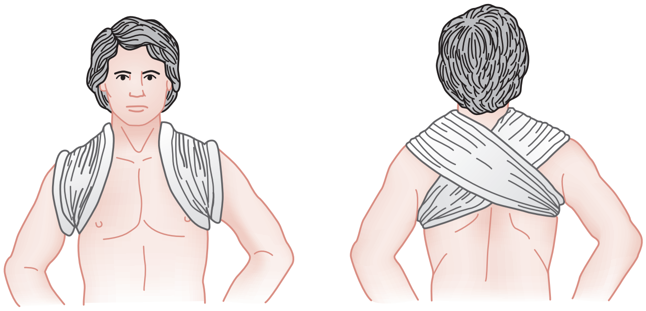

Figure 53-12. Clavicular or figure-of-eight splint.

Examine thoroughly for any tenting of the skin, as this can cause pressure necrosis and progression to an open fracture. Although associated neurovascular injury is rare, the close proximity of the subclavian vessels and brachial plexus demands a thorough assessment. Associated pneumothorax and pulmonary injuries are also rare unless an open or medial third fracture is present.[14] Clavicle-specific plain radiographs should be obtained to confirm the presence of a fracture.[12] The newborn clavicle fracture sustained during birth classically manifests as an uneventful "lump," representing the area of subsequent callus formation, in a child brought in by a concerned parent. Fractures in children, especially neonates, can also be reliably diagnosed or ruled out by bedside ultrasound, sparing the infant exposure to radiation (Fig. 53-10).

Management. Principles of initial management include pain control, immobilization, and proper follow-up care. Fractures of the clavicle can be immobilized with supportive devices, such as a simple sling or sling and swathe (Fig. 53-11). Another immobilization technique for midclavicular fractures still recommended in the orthopedic literature, although its efficacy is not supported by evidence, is the clavicular (figure-of-eight) splint (Fig. 53-12). This splint is applied after closed reduction of the fracture, which is accomplished by pulling the shoulders up and back. Such reductions are difficult to maintain and may be associated with increased discomfort at the fracture site. Use of clavicular splints also can lead to skin irritation and compression of the neurovascular bundle in the axilla. Because some degrees of malunion and shortening are associated with an acceptable functional and cosmetic outcome, treatment with a simple sling is a valid and appropriate alternative to the clavicular splint in the ED.

Disposition. Immediate orthopedic consultation should be sought for open fractures or fractures associated with neurovascular injuries, skin tenting, or interposition of soft tissues. More urgent orthopedic consultation (before 72 hours) is recommended for type II lateral clavicle fractures because these fractures have up to a 30% incidence of nonunion and may require surgical repair.[13] Severely comminuted or displaced fractures of the middle third (defined as over 20 mm of initial shortening) may also benefit from early orthopedic referral for consideration of operative reduction, because these have been associated with a higher incidence of nonunion and long-term functional deficits.[14,15] Additional risk factors that have been associated with nonunion in midclavicular fractures include female gender and advancing age.[16]

www.ketabpezeshki.com 66485457-66963820

Greenstick fractures of the midclavicle are common in children (Fig. 53-13). Most of these fractures are nondisplaced and heal uneventfully. Initial radiographs may appear normal despite suggestive clinical findings. In these instances, the arm should be immobilized in a simple sling and the radiographic evaluation repeated in 7 to 10 days if pain persists, to evaluate for early callus formation.

Most fractures of the clavicle heal uneventfully, and follow-up can be provided by a primary care physician. A sling should be worn until repeat radiographs show callus formation and healing across the fracture site. Early passive shoulder range-of-motion exercises (Fig. 53-14) are encouraged to reduce the risk of adhesive capsulitis (so-called "frozen shoulder"). Younger children generally require shorter periods of immobilization (2 to 4 weeks) than adolescents and adults (4 to 8 weeks). Vigorous competitive play should be avoided until the bone healing is solid. Full range of motion of the shoulder and an absence of pain are two good clinical signs that the fracture has healed.

Figure 53-13. Greenstick fracture of the clavicle *(arrow)*.

Complications. The most common complications are delayed union, nonunion, and symptomatic malunion.[13,17] Displaced fractures of the middle third have a 15 to 20% rate of nonunion and up to 25% rate of symptomatic malunion.[15] Vascular complications after fractures of the medial third can resemble those associated with posterior sternoclavicular dislocations. Articular surface injuries (type III lateral clavicle fractures) can lead to subsequent osteoarthritis of the ACJ.

An uncommon but important association is that between clavicle fractures and atlantoaxial rotatory displacement (AARD). Most cases occur in girls younger than 10 years. The pathophysiology may involve a lax or disrupted alar ligament along with sternocleidomastoid spasm. Early diagnosis is important because delayed diagnosis can lead to a chronic deformity requiring surgical correction. AARD should be suspected if the child has a clavicle fracture and demonstrates a "cocked-robin" position with the head bent toward the fractured side but rotated in the opposite direction. The injury is best demonstrated by CT and, if recognized early, can be treated with a soft cervical collar or halo traction.[18]

Scapula

Pathophysiology. Fractures of the scapula are rare, with an annual incidence of 10 to 12 per 100,000 population.[19] They account for 1% of all fractures and occur primarily in men 30 to 40 years old.[8] In general, considerable force and energy are required to

fracture the body and neck of the scapula. Common mechanisms of injury include high-speed MVCs and falls from height.[20] Coracoid process fractures are usually avulsive, and glenoid rim fractures are commonly associated with anterior glenohumeral dislocations. Acromial or spinous process fractures result from blunt trauma to the top of the shoulder.[21]

The most important aspect of scapular fractures is the high incidence (75-98%) of associated injuries to the ipsilateral lung, chest wall, and shoulder girdle complex.[8,20] The most common associated orthopedic injuries are fractures of the ribs, proximal humerus, and clavicle. Associated lung injuries, including pneumothorax, hemothorax, and pulmonary contusion, usually occur acutely but may manifest in delayed fashion, 2 to 3 days after the initial injury. Associated injuries of the head, spinal cord, brachial plexus, and subclavian or axillary vessels are more significant but less common.[8,20] Of note, in a large series of blunt trauma admissions, the prevalence of aortic injury was similar in patients with or without a fractured scapula.[20]

Fractures of the scapula have traditionally been classified according to their anatomic location. Fractures can involve the acromion process, scapular spine, or coracoid process. Fractures can also involve the scapular neck (Fig. 53-15), glenoid fossa (intra-articular), and scapula body. Recently the Orthopaedic Trauma Association proposed a more comprehensive classification system that allows for a better understanding of severity and prognosis associated with these fractures. Fractures are divided into two main types: extra-articular and intra-articular (with partial or total glenoid involvement).[22]

Clinical Features. In a conscious patient, the shoulder is adducted and the arm is held close to the body. Any attempts at movement result in significant pain. Associated tenderness, crepitus, or hematoma may be noted over the fracture site. The clinical findings occasionally mimic those with a rotator cuff tear. Hemorrhage into the rotator cuff associated with the scapula fracture can result in spasm and a temporary reflex inhibition of function (pseudorupture).[21] The presence of a scapula fracture should prompt a thorough search for associated thoracic, intracranial, orthopedic, and neurovascular injuries.

Diagnostic Strategies: Radiology. The three-view trauma shoulder series will reveal most scapular fractures, as will careful examination of the scapula on the trauma chest radiograph. The true AP view best evaluates the glenohumeral joint, glenoid neck, and scapular body. The transscapular lateral view may demonstrate displacement of the glenoid and scapular body. The axillary lateral view is especially useful in evaluating fractures of the glenoid fossa and the acromion or coracoid process.[8,21] An os acromiale (unfused acromial process epiphysis) is present in 3% of the population and should not be confused with a fracture of the acromion.[6] A comparison film can be useful because the abnormality is present bilaterally in 60% of cases. In many patients, fractures of the scapula initially are overlooked despite being readily apparent on the initial supine trauma chest radiograph because of the life-threatening nature of the associated injuries.[8] Although additional dedicated scapula views can be obtained in the ED, the presence as well as the extent of scapular injury is best determined by CT. In the event that a trauma chest CT scan has been obtained to search for associated injuries, a three-dimensional reconstruction of the scapula should be requested to further define the nature and extent of the injury.[21,23]

Management. Most fractures, including fractures with severe comminution and displacement, heal rapidly with conservative therapy.[8,22] Initial therapy consists of analgesia and immobilization in a sling to support the ipsilateral upper extremity. Passive (see Fig. 53-14) followed by active range-of-motion shoulder exercises should be initiated as soon as discomfort subsides, to reduce the risk of adhesive capsulitis. Most patients require a sling for 2 to 4 weeks and close radiographic follow-up for assessment for delayed displacement.[21]

Fractures of the body and spine usually require no further therapy. Nondisplaced fractures of the acromion process also respond well to conservative therapy. Displaced acromial fractures that impinge on the glenohumeral joint require surgical management. Rarely, the acromion is fractured as part of a superior dislocation of the humeral head. In these instances, an accompanying tear of the rotator cuff is invariably present and requires surgical repair. If the coracoclavicular ligaments remain intact, fractures of the coracoid process respond well to conservative therapy. Severely displaced coracoid fractures with ruptured coracoclavicular ligaments usually require open reduction and internal fixation. Scapular neck and glenoid fossa fractures present the most difficult management issues. Although most of these injuries also do well with conservative therapy, open reduction and internal fixation may be recommended for severely displaced or angulated fractures.[21]

In a review of 520 scapula fractures from 22 case series, Zlowodzki and co-workers reported that 80% of all fractures with glenoid involvement were treated operatively, whereas 83% of all neck injuries and 99% of all isolated scapula body fractures were treated nonoperatively.[19]

Complications. Associated injuries of the ipsilateral lung, chest wall, and shoulder girdle account for most complications after fractures of the scapula. A shear-type brachial plexus injury has been associated with fractures of the acromion process. Neurovascular (brachial plexus, axillary artery) injuries also have been reported with fractures of the coracoid process, scapular neck, body, or spine fractures that extend into the suprascapular notch to injure the suprascapular nerve. The most common presenting symptom of a suprascapular nerve injury is dull posterior shoulder pain that is worsened by activity. The characteristic examination finding is atrophy of the scapular muscles along with weakness in abduction and external rotation Delayed complications include adhesive capsulitis and rotator cuff dysfunction.

Proximal Humerus

Pathophysiology. Fractures of the proximal humerus are common and account for 4 to 5% of all fractures.[24] An epidemiologic Swedish study reported an incidence of 14 to 60 per 100,000 per year, with a mean age at occurrence of 63 years and a female-to-male ratio of 1.5 : 1.[25] These fractures occur primarily in the older population, in whom structural changes associated with aging (osteoporosis) weaken the proximal humerus, predisposing it to

www.ketabpezeshki.com 66485457-66963820

injury. Although most of these injuries involve minimal displacement and are adequately managed with conservative therapy, significantly displaced fractures may require operative intervention. Displacements encountered with fractures of the humerus usually reflect the pull of the attached muscle group.

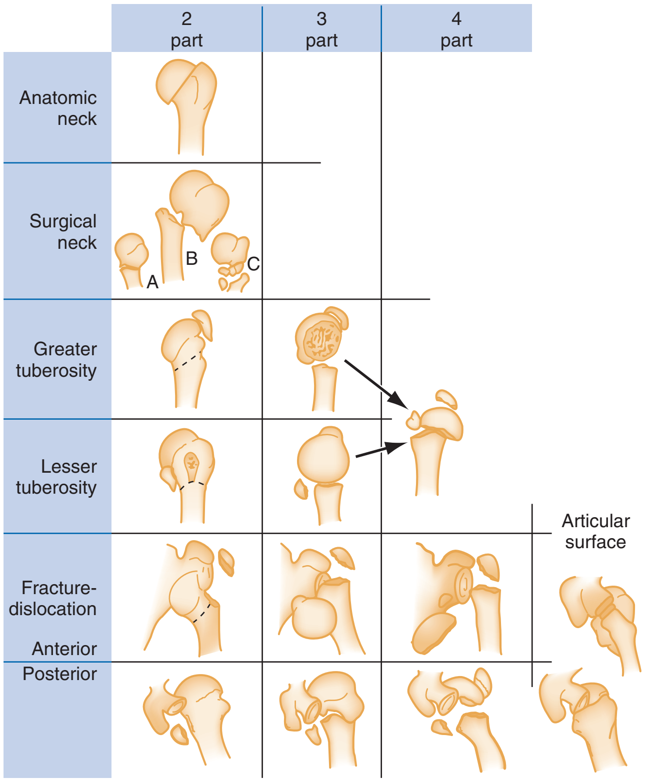

Figure 53-16. Neer's classification of proximal humeral fractures. (From Neer CS: Displaced proximal humeral fractures: Part 1. Classification and evaluation. J Bone Joint Surg Am 52:1077, 1979.)

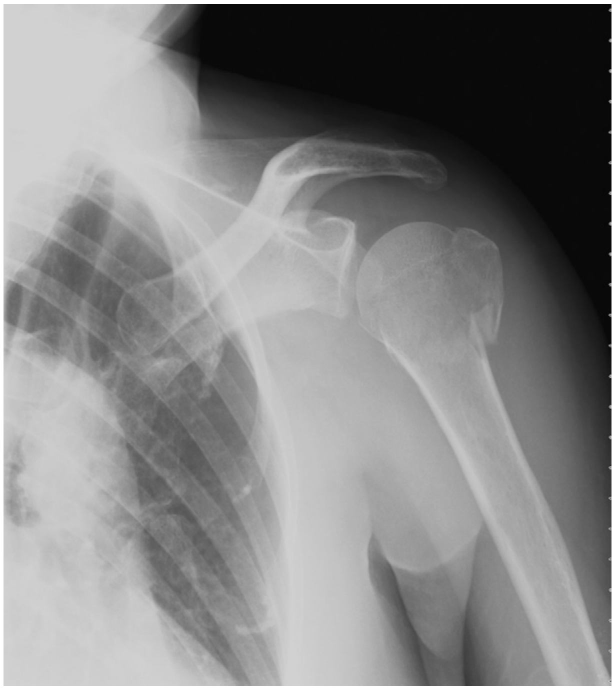

Figure 53-17. Three-part minimally displaced fracture of the proximal humerus involving the greater and lesser tuberosities.

Fractures of the proximal humerus separate along old epiphyseal lines, producing four distinct segments consisting of the articular surface (anatomic neck), greater tuberosity, lesser tuberosity, and humeral shaft (surgical neck). Neer's classification system (Fig. 53-16) is based on the relationship of these fracture fragments.[24] In this system, a segment is considered displaced if it is angled more than 45 degrees or separated more than 1 cm from the neighboring segment. Because this classification system considers only displacement, the number of fracture lines is irrelevant. There are four major categories of fracture: minimal displacement (Fig. 53-17), two-part displacement (Fig. 53-18), three-part displacement, and four-part displacement. When present, anterior and posterior dislocations are included as part of the classification. Impaction and head-splitting fractures are classified separately.

The classic mechanism of injury involves a fall on an outstretched abducted arm. Concurrent pronation limits further abduction and levers the humerus against the acromial process; this produces a fracture or dislocation, depending on the tensile strengths of the bone and surrounding ligaments. Older patients are prone to fracture, whereas younger persons are apt to have dislocations. The combined injury (fracture and dislocation) may be seen in middle-aged patients. Proximal humerus fractures also may result from a direct blow to the lateral side of the arm or from an axial load transmitted through the elbow. High-energy mechanisms and polytrauma are more common in younger persons.

Clinical Features. The affected arm is held close to the body, and movement is restricted by pain. Tenderness, hematoma, ecchymosis, deformity, or crepitus may be noted over the fracture site. A

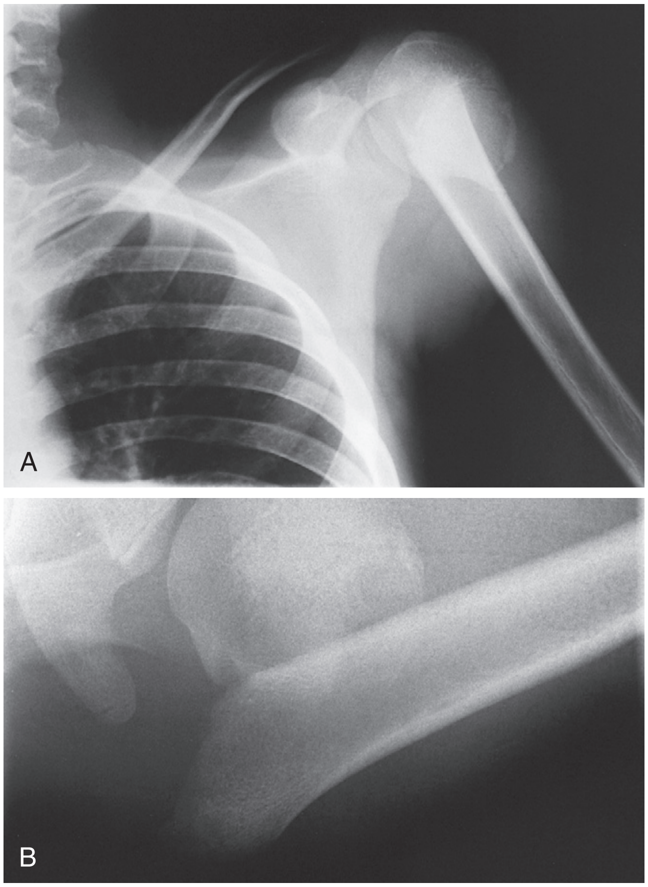

Figure 53-18. Anteroposterior (A) and axillary (B) radiographic views of a two-part displaced fracture of the proximal humerus. The degree of displacement often is better visualized on the axillary view. (Courtesy David Nelson, MD.)

www.ketabpezeshki.com 66485457-66963820

thorough neurovascular examination is essential to identify associated injuries of the axillary nerve, brachial plexus, or axillary artery (see Table 53-1). The three-view trauma series of shoulder radiographs will allow for assessment of the number of fracture fragments and degree of displacement or angulation.

Management. Minimally displaced fractures (see Fig. 53-17) constitute 80 to 85% of all cases. In these instances, limited displacement or angulation is present, and the fracture segments are held together by the capsule, periosteum, and surrounding muscles. Initial treatment consists of adequate analgesia and immobilization with a sling or sling and swathe device. The former is more comfortable, and a Cochrane review of 16 randomized trials found only limited evidence that use of special bandage immobilization affected time to fracture union or functional outcome.[26] Traditionally, it has been recommended that immobilization be continued until clinical union is achieved (head and shaft are seen to move together). The Cochrane review also noted that immediate or earlier commencement of physiotherapy (within 1 week) resulted in less pain and did not compromise long-term outcome. Initial passive exercises (see Fig. 53-14) are gradually replaced by more active and resistive exercises. Most nondisplaced fractures heal over 4 to 6 weeks.

The treatment of two-part, three-part, and four-part displaced fractures is beyond the scope of this discussion. An orthopedic surgeon should be consulted, because many of these injuries require operative repair.[24] Prospective and retrospective observational studies, however, have failed to show a significant functional difference between operative and nonoperative treatment of displaced two-part and three-part fractures in elderly patients. Current literature continues to support operative treatment of four-part fractures in the elderly; the procedure of choice is hemiarthroplasty.[26]

Fracture-dislocation injuries (Fig. 53-19) are best managed in consultation with an orthopedic surgeon before attempts at reduction (except in cases of neurovascular compromise or unavailability of an orthopedic surgeon). Of note, reductions of these injuries in the ED often are unsuccessful, and these manipulations can cause separation of previously undisplaced segments. Closed reduction under radiologic control and general anesthesia may be preferable.

Posterior glenohumeral dislocations usually are associated with anteromedial impression fractures of the articular surface. A similar fracture of the posterolateral aspect of the humeral head is present with anterior dislocations (Hill-Sachs deformity). Impression fractures involving less than 20% of the articular surface usually are stable. With more than 20% involvement, the reduction usually is unstable and requires surgical repair.

Complications. The most common complication of proximal humeral fractures is adhesive capsulitis. This complication can be prevented by the early initiation of pendular shoulder exercise, along with a thorough rehabilitation program. One of the most devastating complications is avascular necrosis (AVN) of the humeral head. The highest rate of AVN (up to 90%) has been documented for four-part fractures.[27] Repeated forceful attempts at reduction of fracture-dislocations may be associated with subsequent heterotopic bone formation (myositis ossificans). Neurovascular injuries (axillary nerve, brachial plexus, and axillary artery) may be encountered with displaced surgical neck fractures and fracture-dislocations.

Proximal Humeral Epiphysis

Pathophysiology. Fractures of the proximal humeral epiphysis are uncommon and account for less than 1% of all pediatric fractures.[28] The injury can occur at any age while the epiphysis remains open but is most common in adolescent boys. The most common mechanism of injury involves a fall onto the outstretched hand, and the fracture typically occurs through the zone of hypertrophy in the epiphyseal plate. Injuries can be classified according to their location (Salter system), stability, and degree of displacement.

Clinical Features. The patient holds the injured arm tightly against the body by the opposite hand. The area over the proximal humerus is swollen and extremely tender to palpation. Radiographs obtained at 90 degrees to each other confirm the diagnosis.

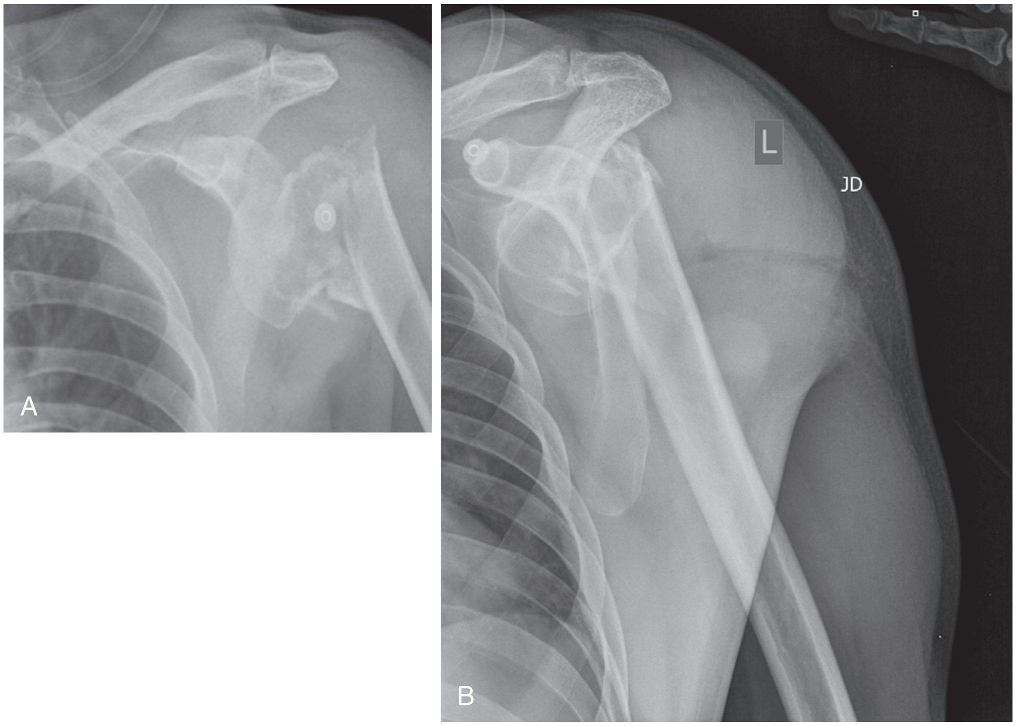

Figure 53-19. Two-part fracture and dislocation of the proximal humerus; anteroposterior (A) and transscapular lateral (B) radiographic views.

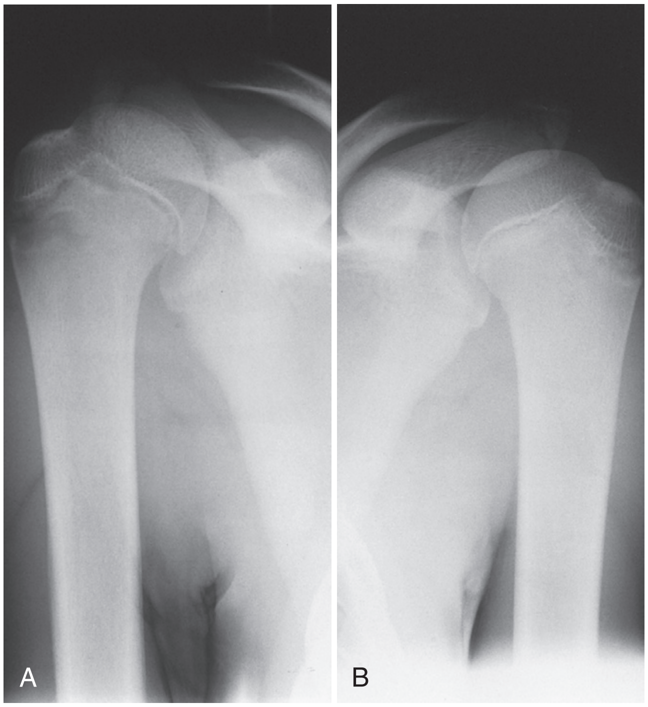

Figure 53-20. **A,** Salter I injury of the right proximal humeral epiphysis. **B,** Normal left side is included for comparison.

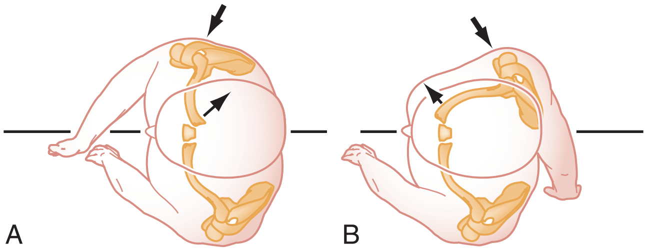

Figure 53-21. Mechanisms that produce anterior and posterior displacements of the sternoclavicular joint. **A,** When the patient is lying on the ground and a compression force *(upper arrow)* is applied to the posterolateral aspect of the shoulder, the medial end of the clavicle is displaced posteriorly *(lower arrow).* **B,** When the lateral compression force *(upper arrow)* is directed from the anterior position, the medial end of the clavicle is dislocated anteriorly *(lower arrow).* The same mechanism could apply with any type of lateral compression injury of the shoulder. (From Neer CS, Rockwood CA: Fractures and dislocations of the shoulder. In Rockwood CA, Green DP (eds). Fractures in Adults, 4th ed. Philadelphia, JB Lippincott, 1984.)

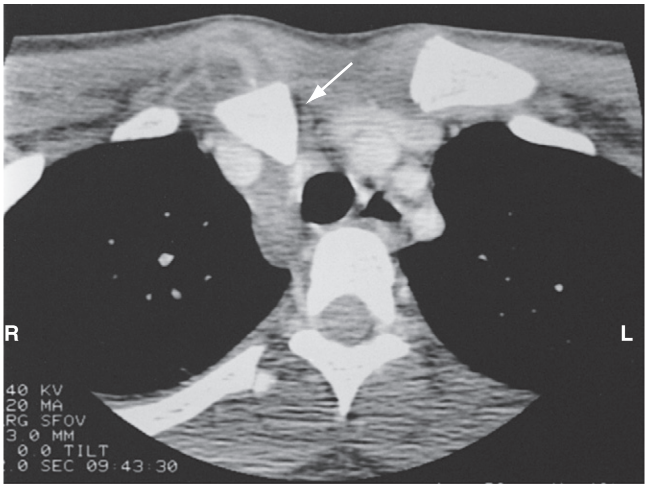

Figure 53-22. This computed tomography scan shows posterior dislocation of the right sternoclavicular joint *(arrow)* with compression of the superior mediastinum. (Courtesy Donald Sauser, MD.)

Comparison views may be helpful with minimally displaced fractures. Bedside ultrasound has also been shown to detect these injuries. In one series of 100 shoulder injury subjects, all three cases of proximal humerus fractures were detected by ultrasound imaging (sensitivity 83-93%) before shoulder radiographs had been obtained.[12]

Management. Fractures of the proximal humeral epiphysis should not be taken lightly, because the physis accounts for 80% of the growth of the bone. The active healing process at the site of an epiphyseal injury makes delayed reduction extremely difficult. Early orthopedic consultation should be obtained for all such injuries. Children younger than 6 years usually have Salter I epiphyseal injuries (Fig. 53-20), which can be treated conservatively with sling and swathe immobilization and analgesic agents. Children older than 6 years usually have a Salter II epiphyseal injury. Salter II injuries with more than 20 degrees of angulation may benefit from reduction, which is accomplished by reversing the mechanism of injury.[28] Imperfect reductions often are acceptable because growth and remodeling correct the deformity with time. After reduction, unstable injuries should be immobilized in a shoulder spica cast, whereas stable lesions can be immobilized with a sling and swathe. Fractures of the proximal humeral epiphyses generally heal in 3 to 5 weeks.[28]

Complications. Complications are rare and include malunion, growth plate disturbances, and injuries to the neurovascular bundle. Markedly displaced or angulated fractures are more likely to result in a residual loss of mobility.

Dislocations

Sternoclavicular

Pathophysiology. SCJ dislocations are infrequent and account for less than 1% of all dislocations.[29] Significant forces are required to disrupt the strong ligamentous stabilizers of this joint. The most common causes are MVCs and injuries sustained in contact sports. The SCJ can dislocate in an anterior or a posterior direction. Anterior dislocations, which result from indirect forces, are more common (9:1 ratio).[5] The usual mechanism of injury (Fig. 53-21) involves an anterolateral force to the shoulder, followed by backward rolling, which levers the medial clavicle out of its articulation. Posterior dislocations (Fig. 53-22) can result from a direct blow to the medial clavicle (30%) or from delivery of a posterolateral force to the shoulder, followed by inward rolling (70%). Posterior dislocations can be associated with life-threatening injuries within the superior mediastinum, including acute airway compression.

Injuries to the SCJ can be graded into three types.[5] A grade I injury is a mild sprain secondary to stretching of the sternoclavicular and costoclavicular ligaments. A grade II injury is associated with subluxation of the joint (anterior or posterior) secondary to rupture of the sternoclavicular ligament. The costoclavicular ligament remains intact. Complete rupture of the sternoclavicular and costoclavicular ligaments results in a grade III injury (dislocation). In patients younger than 25 years, these actually represent Salter type I injuries, because the medial epiphysis of the clavicle has not yet fused.[30]

Clinical Features. Clinical suspicion is the most important factor in diagnosing these injuries, and prompt diagnosis is vital because

www.ketabpezeshki.com 66485457-66963820

it is associated with a better prognosis. The injured extremity is flexed at the elbow and supported across the trunk by the opposite arm. Pain results from any movement of the upper extremity or lateral compression of the shoulders. The SCJ may be mildly swollen and tender to palpation. With an anterior dislocation, the displaced medial end of the clavicle may be palpable. Posterior dislocations are associated with more severe pain, and the neck is often flexed toward the injured side.[30] The clavicular notch of the sternum may be palpable, and complaints of hoarseness, dysphagia, dyspnea, and weakness or paresthesias in the upper extremities have been documented. Rarely, airway complications caused by tracheal injury may be present. If present, airway compromise should be attended to promptly. These patients should also be examined thoroughly to identify any injuries to superior mediastinal or intrathoracic structures. The presence of cyanosis and venous congestion of the neck and arm is typical of an innominate vein injury.[30] When necessary, appropriate consultation should be obtained.

Diagnostic Strategies: Radiology. Although the diagnosis of sternoclavicular dislocation can be made clinically, it should be confirmed radiologically. Findings on standard AP, oblique, and specialized (40-degree cephalic tilt) views often are difficult to interpret because of overlapping rib, sternum, and vertebral shadows. These dislocations and associated injuries are best visualized by CT (see Fig. 53-22). Ultrasound imaging also may be a useful adjunct in some circumstances.[5]

Management. Treatment of grade I injuries includes immobilization (simple sling), adequate analgesia, and primary care follow-up. Immobilization generally is maintained (1-2 weeks) until full painless motion is restored. Grade II injuries should be immobilized with a sling or soft clavicular (figure-of-eight) splint (see Fig. 53-12) and the patient referred for orthopedic follow-up care. The figure-of-eight splint is preferred because it maintains the clavicle in a more anatomic position and permits ligament healing. Grade II injuries require a longer course of immobilization (3-6 weeks) and are more likely to be associated with persistent pain.[5] All grade III injuries should be managed by closed reduction.

Anterior dislocations may be reduced in the ED after orthopedic consultation and intravenous analgesia (Fig. 53-23). A rolled sheet is placed posteriorly between the shoulder blades to elevate both shoulders approximately 5 cm above the table. Traction is applied to the arm in an extended (10- to 15-degree) and abducted (90-degree) position. If reduction does not occur, an assistant can add inward pressure on the medial end of the clavicle. Stable reductions should be maintained in a clavicular splint, and the patient referred for orthopedic follow-up care.[30] Most reductions are unstable. Because the deformity is primarily cosmetic and not functional, the current treatment of choice for recurrent anterior dislocations is benign neglect.

Posterior dislocations constitute true orthopedic emergencies and should be reduced expeditiously.[5,30] Ideally, reduction of posterior dislocations should be attempted in the operating room with the patient under general anesthesia, although it can be attempted in the ED with use of procedural sedation. Emergency reduction may be required for patients with airway obstruction or vascular compromise. The patient is positioned as described previously, and traction is applied in an extended and abducted position. If traction alone does not reduce the dislocation, concurrent clavicular manipulation may be helpful. After sterile preparation of the skin and administration of local anesthesia, the clavicle shaft is grasped with a sterile towel clip and pulled out anterolaterally. Once reduced, these injuries generally are stable and can be immobilized with a clavicular splint. An alternate method of reduction involves traction to the adducted injured arm while both shoulders simultaneously are forced posteriorly with direct pressure.[31] This technique levers the clavicle into place and requires much less force than the traditional abduction-extension method.

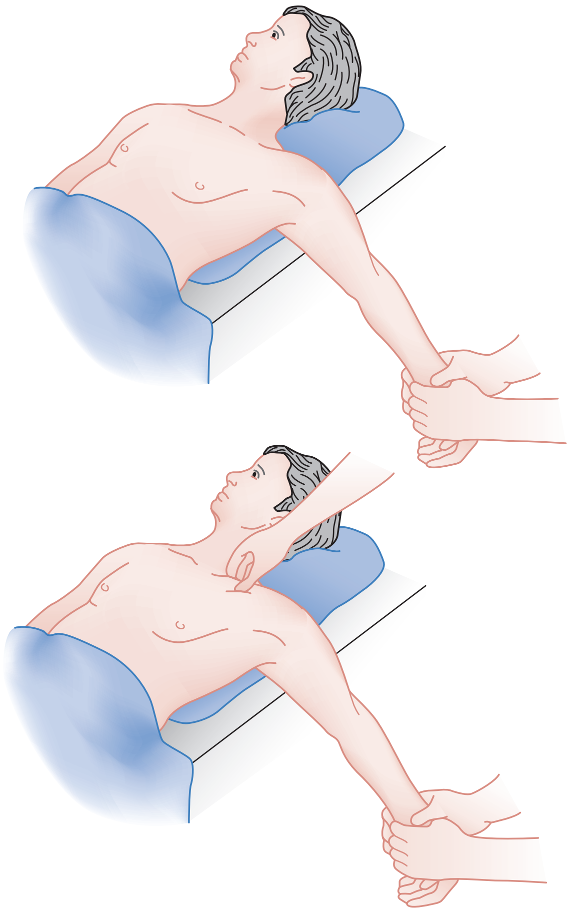

Figure 53-23. Reduction of dislocated sternoclavicular joints. (From Simon RR, Koenigsknecht SJ: Emergency Orthopedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

Complications. Complications of anterior injuries are primarily cosmetic. By contrast, 30% of posterior dislocations may be complicated by life-threatening injuries to intrathoracic and superior mediastinal structures.[30] Complications include compression or laceration of the great vessels, tracheoesophageal fistula, tracheal compression, pneumothorax, thoracic outlet syndrome, and brachial plexus injuries. These injuries are best visualized though a chest CT angiogram. A potential long-term complication of both anterior and posterior injuries is degenerative osteoarthritis, which manifests with pain and swelling over the joint or pain on shoulder movement.

Acromioclavicular Joint

Pathophysiology. Injuries of the ACJ occur primarily in young men as a result of participation in contact sports, such as football, rugby, ice hockey, and wrestling. A small percentage of injuries are caused by MVCs and falls.

The most common mechanism of injury involves a fall or direct blow to the point of the shoulder with the arm adducted. The resultant force drives the scapula downward and medially to produce the injury. The weak acromioclavicular ligaments rupture first. With increasing force, the coracoclavicular ligament ruptures, and the attachments of the deltoid and trapezius muscles are torn from the distal clavicle. The ACJ also can be injured after a fall onto the outstretched hand. In this instance, the force is

www.ketabpezeshki.com 66485457-66963820

transmitted to the acromioclavicular ligaments only, and the coracoclavicular ligament, which is relaxed, remains uninjured.

Classification is based on the degree of damage sustained by the acromioclavicular and coracoclavicular ligaments (Fig. 53-24). The most commonly used system is that modified by Rockwood.[32] Type I injuries are sprains of the acromioclavicular ligaments with no separation of the acromion and clavicle. Type II injuries are associated with disruption of the acromioclavicular ligaments. The joint space is widened, and the clavicle is displaced slightly upward. There are minor tears in the attachments of the deltoid and trapezius muscles, but the coracoclavicular ligament remains intact, and the coracoclavicular distance is maintained. A type III injury is characterized by complete disruption of the acromioclavicular ligaments, coracoclavicular ligament, and muscle attachments. The joint space is widened, and the coracoclavicular distance is increased by 25 to 100%. The clavicle is displaced upward by the pull of the trapezius, and the shoulder is displaced downward by the effect of gravity. In type IV and V injuries, the ligamentous and muscle disruptions are similar to the disruptions encountered in type III injuries, but the clavicle is displaced either posteriorly into the trapezius (type IV) or superiorly in an exaggerated fashion (coracoclavicular distance increased 100 to 300%; type V). In the rare type VI injury, the clavicle is displaced inferiorly.

Clinical Features. Patients should be examined while they are in the sitting or standing position because the supine position can mask ACJ instability. It is helpful to visualize both shoulders simultaneously to assess for symmetry. Type I and type II injuries are associated with mild tenderness and swelling over the ACJ margin, with minimal deformity. A full range of motion often is possible, although painful. Patients with type III, IV, V, and VI injuries usually have severe pain and hold the arm tightly adducted to reduce traction stress across the joint. In type III injuries, the shoulder hangs downward and the clavicle rides high, producing a characteristic clinical deformity. In type IV injuries, the clavicle may be palpable posteriorly, and in type V injuries, the clavicle may be palpable subcutaneously above the acromion. In type VI injuries, the shoulder assumes a flattened clinical appearance as seen from the side.

Diagnostic Strategies: Radiology. The energy settings used for the three-view shoulder trauma series usually overpenetrate the ACJ. Specific ACJ views that use one-third to two-thirds less intensity should be ordered. The recommended projections include an AP view of both joints on a single wide film, an axillary lateral view, and a 15-degree cephalic tilt view.[32] The axillary lateral view is useful for identifying associated fractures and posterior dislocation of the clavicle. The normal coracoclavicular distance ranges from 11 to 13 mm. A difference of more than 5 mm between the injured and uninjured sides is diagnostic of a complete coracoclavicular disruption. With type I injuries, the radiographic appearance is essentially normal. With type II injuries, radiographs show widening of the joint and a slight upward or posterior displacement of the clavicle but a normal coracoclavicular distance. Type II injuries are often subtle and can be easily overlooked. With type III, IV, and V injuries, radiographic features include a widened joint, an increased coracoclavicular distance, and either superior or posterior displacement of the clavicle (Fig. 53-25). Historically, stress views of the ACJ have been recommended to differentiate between type II and type III injuries. Such views lack efficacy for this purpose, and their routine use is unnecessary.[33]

Management. Type I and II injuries should be immobilized in a sling for comfort and to protect against further injury. Patients with these injuries should be referred for follow-up with their primary care physician. When pain has subsided (1 to 3 weeks), range-of-motion and strengthening exercises can begin, with a return to sports when pain-free function has been achieved.

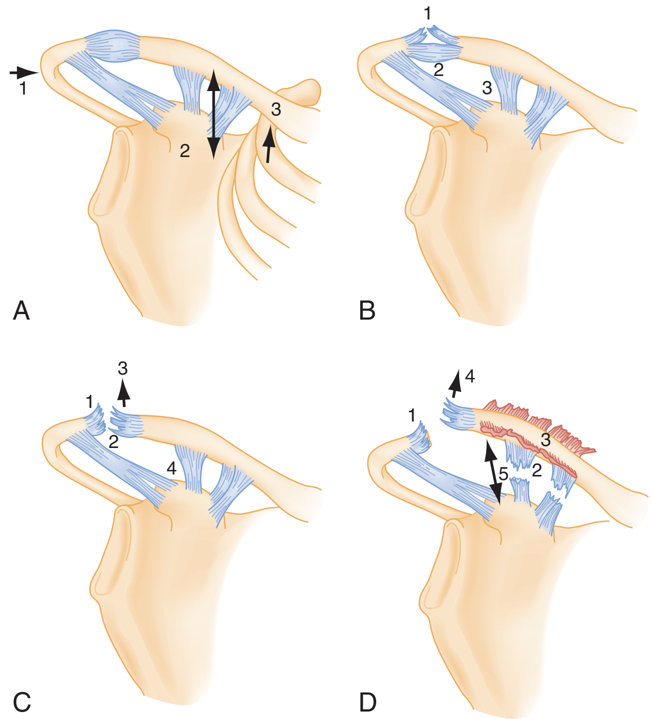

Figure 53-24. Mechanism of injury and classification of acromioclavicular joint injuries. Arrows indicate direction of applied force and relevant movement. **A,** The direct force is applied to the point of the shoulder *(1);* the scapula and attached clavicle are forced downward and medially; the clavicle approaches the first rib *(2).* If the force continues, the first rib abuts the clavicle, producing a counterforce *(3).* Depending on the magnitude of the force, a grade I, II, or III sprain may occur. **B,** Grade I sprain. A few fibers of the acromioclavicular ligament stretch, and a few tear *(1);* the acromioclavicular joint is stable *(2);* the coracoclavicular ligament is intact *(3).* **C,** Grade II sprain (subluxation). The capsule and the acromioclavicular ligament rupture *(1);* the joint is lax and unstable *(2);* the end of the clavicle rides upward, with displacement usually less than half of the width of the end of the clavicle *(3);* the coracoclavicular ligament remains intact *(4);* the attachments to the trapezius and deltoid remain intact. **D,** Grade III sprain (dislocation). The capsule and acromioclavicular ligaments rupture *(1);* the coracoclavicular ligament ruptures *(2);* the insertions of the trapezius and deltoid tear away *(3);* the clavicle rides upward *(4);* the interval between the clavicle and the coracoid process is greatly increased *(5).* (From DePalma AF: Surgery of the Shoulder, 3rd ed. Philadelphia, JB Lippincott, 1983.)

www.ketabpezeshki.com 66485457-66963820

Type IV, V, and VI injuries require early surgical treatment. The management of type III injuries has changed dramatically since the 1980s. Most studies have concluded that conservative treatment provides functional results equivalent to or, in some cases, better than those obtained with surgical intervention. In addition, surgical patients have longer recovery times and higher complication rates.[7] The main complications of conservative therapy are the persistence of nuisance symptoms (clicking or minor pain) and a cosmetic deformity. Selected patients who are young, have severe displacement (more than 2 cm), and perform repetitive overhead activities may be candidates for surgical intervention.[7] Treatment of type III injuries in the ED should consist of sling immobilization and early orthopedic referral (within 72 hours) if the patient is deemed to be a potential surgical candidate. The initial therapy in all cases should include adequate analgesia.

Complications. The most common concurrent injuries are associated fractures of the clavicle and coracoid process. The most common complications of ACJ injuries are residual symptomatic instability and tenderness over the joint caused by secondary degenerative changes.[7,33] Acromioclavicular arthritis typically manifests as an impingement syndrome with shoulder pain between 120 and 180 degrees of abduction.

Glenohumeral Dislocations

Perspective. The glenohumeral joint is the most commonly dislocated major joint in the body. The lack of intrinsic bone stability in conjunction with its wide range of motion predisposes the joint to dislocations. The annual incidence is 17 per 100,000, and two distinct age peaks are recognized, the first in men 20 to 30 years of age and the second in older women.[34] The glenohumeral joint can dislocate anteriorly, posteriorly, inferiorly, or superiorly. Anterior dislocations account for 95 to 97% of all glenohumeral dislocations. Posterior dislocations account for most of the remainder, whereas inferior and superior dislocations are rare.

Anterior Dislocations

Pathophysiology. Anterior dislocations can result from indirect or direct forces. The most common mechanism of injury consists of an indirect force transferred to the anterior capsule from a combination of abduction, extension, and external rotation. In younger persons, the injury usually is sustained during athletic activities involving rapid movements, and a characteristic pathologic feature is avulsion of the anteroinferior glenohumeral ligament with capsulolabral detachment (Bankart's lesion).[34] In older patients, a fall onto the outstretched arm is the more common mechanism of injury, and an accompanying rotator cuff tear is common.[34] Rarely, a direct force applied to the posterolateral aspect of the shoulder can force the humeral head out of the glenoid fossa anteriorly.

Anterior dislocations can be classified according to their cause (traumatic or nontraumatic), their frequency (primary or recurrent), and the anatomic position of the dislocated humeral head. After dislocation the humeral head can assume a subcoracoid, subglenoid, subclavicular, or intrathoracic position (Fig. 53-26). The subcoracoid is the most common type of anterior dislocation. The head is displaced anteriorly and rests on the scapular neck inferior to the coracoid process. The next most common type is the subglenoid dislocation, in which the head is anterior and inferior to the glenoid fossa. Together, the subcoracoid and subglenoid types account for 99% of all anterior dislocations. Subclavicular and intrathoracic dislocations are extremely rare and involve the addition of strong lateral to medial forces that push the humeral head medially.

Clinical Features. The patient is in severe pain, with the dislocated arm held in slight abduction and external rotation by the opposite extremity. The lateral edge of the acromion process is prominent, and the normally rounded shoulder assumes a

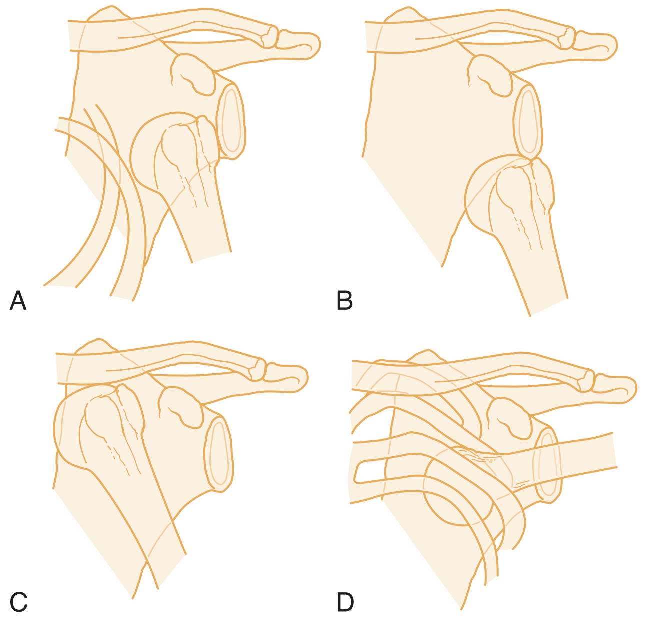

Figure 53-26. Types of anterior dislocation. **A,** Subcoracoid. **B,** Subglenoid. **C,** Subclavicular. **D,** Intrathoracic. (From DePalma AF: Surgery of the Shoulder, 3rd ed. Philadelphia, JB Lippincott, 1983.)

"squared-off" appearance. The coracoid process is indistinct, and the anterior shoulder appears full. The patient leans away from the injured side and cannot adduct or internally rotate the shoulder even slightly without severe pain. A neurovascular examination is performed to identify associated injuries of the brachial plexus, axillary nerve, radial nerve, or axillary artery. The reported incidence of axillary nerve injuries after anterior glenohumeral dislocation ranges from 5 to 54%, and they are more frequent in patients older than 50 years.[35,36] Axillary nerve function can be assessed by testing for sensation over the lateral aspect of the shoulder and by testing motor function of the teres minor and deltoid muscles. Deltoid function is tested by having the patient attempt shoulder abduction while the examiner feels for muscle contraction. Motor testing is more accurate because sensory testing can be misleading owing to the presence of overlapping cutaneous nerve root dermatomes.

Diagnostic Strategies: Radiology. The trauma series of radiographs will confirm the clinical diagnosis and identify the position of the humeral head (Fig. 53-27). Associated fractures may be present in 50% of cases. The most common of these is a compression fracture of the posterolateral aspect of the humeral head caused by forceful impingement against the anterior rim of the glenoid fossa. This defect in the humeral head, or Hill-Sachs deformity (see Fig. 53-27), is reported to be present in 11 to 50% of all anterior dislocations. The actual incidence is probably much higher, because minor compression fractures are difficult to visualize on plain radiographs. The defect is best visualized on an internal rotation AP view of the glenohumeral joint. Although common, Hill-Sachs fractures are of limited clinical significance unless they are large enough to cause recurrent shoulder instability or painful clicking or catching, in which case surgical repair may be necessary. A corresponding fracture of the anterior glenoid rim (Bankart's fracture) is present in approximately 5% of cases.[9] Avulsion fractures of the greater tuberosity are present in 10 to 15% of cases.[9,35]

Management. Reduction of the dislocation should be accomplished expeditiously, because the incidence of neurovascular complications increases with time.[36] Radiographic documentation of the type of dislocation and any associated fractures should

www.ketabpezeshki.com 66485457-66963820

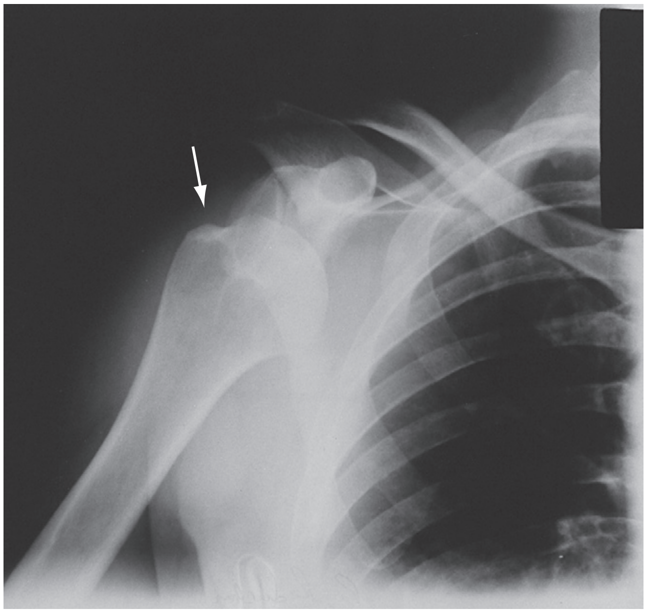

Figure 53-27. Recurrent anterior subcoracoid dislocation with Hill-Sachs deformity of the humeral head *(arrow).*

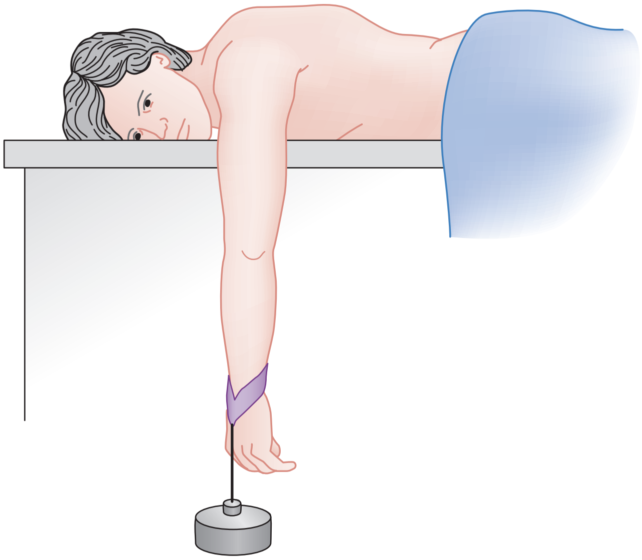

Figure 53-28. Stimson or hanging weight method of reduction for anterior shoulder dislocations.

generally be obtained *before* reduction is attempted. Reduction can be accomplished with various techniques, most of which involve traction, leverage, or scapular manipulation principles.[37] The ideal method should be simple, quick, and effective; require little assistance; and cause no additional injury to the shoulder. It is wise to be familiar with several techniques of reduction, because none is uniformly successful.

Analgesia and muscle relaxation through procedural sedation are often used to facilitate reduction in the ED. Muscle relaxation and analgesia also can be provided through intra-articular injection of a local anesthetic agent. This technique is especially useful when procedural sedation is contraindicated. Under sterile technique, the joint is entered 2 cm inferior to the lateral edge of the acromion with an 18-gauge or 20-gauge needle. Any associated hemarthrosis is aspirated; then 20 mL of 1% lidocaine is injected over 30 seconds. The patient is allowed to relax for 15 minutes before reduction is attempted. The published studies to date all have used lidocaine, although it would be reasonable to expect similar results with other local anesthetic agents such as bupivacaine.

Fitch and Kuhn recently reviewed six randomized controlled trials comparing intravenous sedation and intra-articular lidocaine.[38] Outcomes in these studies included success rates, complications, and time spent in the ED. Although the reduction techniques were not controlled in these studies, none showed a statistical difference in the reduction success rates, which averaged 92% for both the intra-articular lidocaine and intravenous sedation groups. Complication rates were quite different, however, averaging 0.67% in the intra-articular lidocaine group and 13.3% in the intravenous sedation group. The most common in the lidocaine group was "psychological agitation," whereas the sedation group experienced nausea, vomiting, and respiratory depression. Time spent in the ED was significantly less for the intra-articular lidocaine group.[38] Depending on the duration of the dislocation, nature (primary vs. recurrent) and technique, reduction can also be attempted and accomplished successfully without the use of any analgesia or muscle relaxation.[2,37,39]

There are many techniques that can be used for reduction of an anterior shoulder dislocation, some of which are highlighted here.

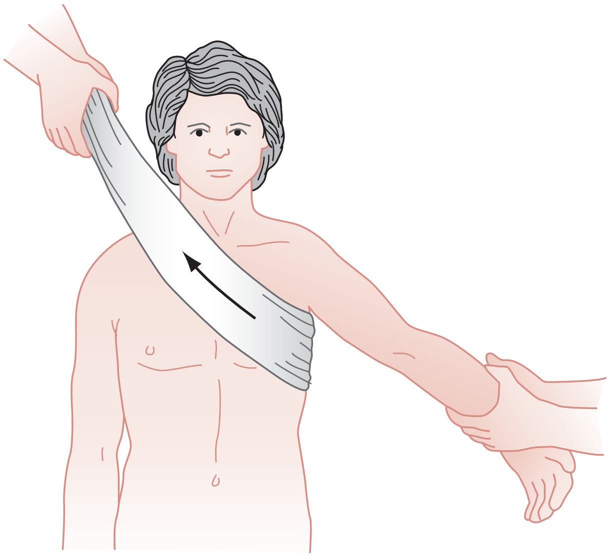

Figure 53-29. Traction-countertraction method for reducing anterior shoulder dislocations.

Most of these techniques are quite effective, but approximately 5 to 10% of dislocations cannot be reduced in the ED.[37] Traction techniques use steady force applied in various directions (forward flexion, abduction, overhead, lateral) to overcome the muscle spasm that holds the humeral head in its dislocated position. In the *Stimson* or *hanging weight technique* (Fig. 53-28), the patient is placed prone with the dislocated arm hanging over the edge of the examining table. A 10- or 15-pound weight attached to the wrist or lower forearm provides traction in forward flexion. Reduction usually occurs over 20 to 30 minutes. In the *traction-countertraction method* (Fig. 53-29), traction is applied along the abducted arm while an assistant using a folded sheet wrapped across the chest applies countertraction. Another simple and effective traction technique is the *Snowbird technique,* which has a reported success rate of 97%.[37] In this method, the patient is seated in a chair and the affected arm is supported by the patient's unaffected extremity. A 3-foot loop of 4-inch cast stockinette is placed

www.ketabpezeshki.com 66485457-66963820

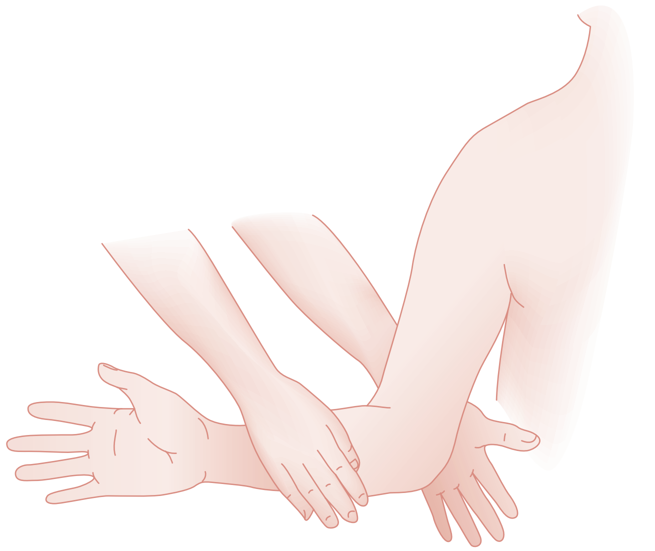

Figure 53-30. External rotation technique for reducing anterior shoulder dislocations. The involved arm is slowly adducted to the patient's side, and the elbow is flexed 90 degrees. Gentle external rotation is applied to the forearm to achieve reduction. (From Simon RR, Koenigsknecht SJ: Emergency Orthopedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

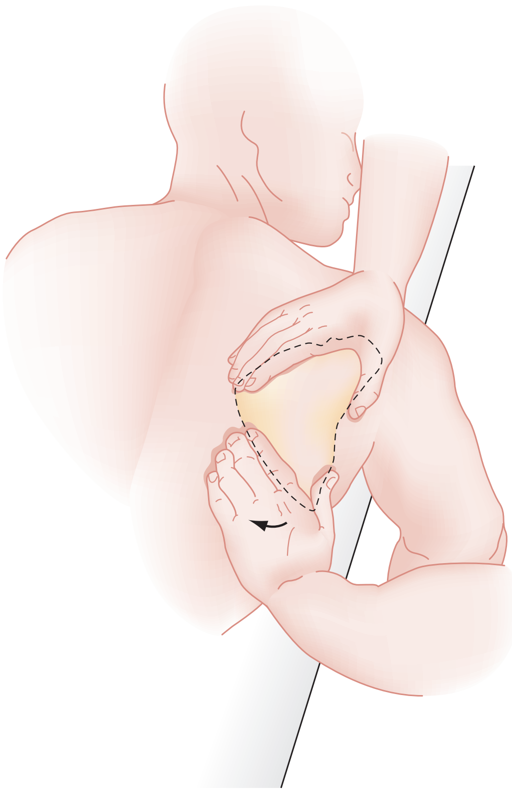

Figure 53-31. Proper hand position and direction of rotation during shoulder relocation via the scapular manipulation technique. Arrow indicates direction of applied force. (From Kothari RU, Dronen SC: The scapular manipulation technique for the reduction of acute anterior shoulder dislocations. J Emerg Med 8:625, 1990.)

along the proximal forearm of the involved extremity with the elbow at 90 degrees. The patient is assisted or instructed to sit up, and the physician's foot is placed in the stockinette loop to provide firm downward traction. The physician's hands remain free to apply any gentle external pressure or rotation as needed until reduction is accomplished.

The most commonly recommended leverage technique is the *external rotation method of Leidelmeyer*.[40] With the patient in the supine position, the involved arm is slowly and gently adducted to the side. The elbow is flexed to 90 degrees, and slow, gentle external rotation is applied to achieve reduction (Fig. 53-30). Success rates with this method range from 80 to 90%.[31] With the *Milch technique*, the patient is placed supine on the gurney and the head of the bed is elevated 20 to 30 degrees. The affected arm is held by the wrist and slowly abducted and externally rotated. The operator stops whenever resistance to motion is encountered and continues when the patient is relaxed. If the humerus has not reduced by the time 90 degrees of abduction and 90 degrees of external rotation have been reached, gentle longitudinal traction is applied along the humerus while the free hand is used to exert lateral and superior pressure on the humeral head to complete the maneuver.[2] Reduction usually takes 5 to 10 minutes and can be accomplished without an assistant or procedural sedation. O'Connor and colleagues[2] recently reported a 100% success rate on first attempt with the Milch technique. The effectiveness of this method has been attributed in part to more conical symmetry of the muscle forces acting across the glenohumeral joint. Several variants of the Milch technique have been reported in the literature.[37,39]

Scapular manipulation accomplishes reduction by repositioning the glenoid fossa rather than the humeral head and can be successful with minimal analgesia or muscle relaxation. Manipulation can be combined with the Stimson or traction-countertraction techniques. After the application of traction (manual or hanging weights), the scapula is manipulated by rotation of the inferior tip medially (Fig. 53-31) while the superior and medial edges are stabilized with the opposite hand. Scapular manipulation can also be used in a seated position in which a second operator applies traction in the forward horizontal position.[31,37] Scapular manipulation can be difficult in heavyset patients, in whom it is difficult to palpate and grasp the inferior tip of the scapula.

More traditional techniques, such as the Hippocratic method (traction with the foot in the axilla) and the Kocher maneuver (leverage, adduction, and internal rotation), are no longer recommended because of a high incidence of associated complications (axillary nerve injury, humeral shaft and neck fractures, capsular damage). Comparative studies of the efficacy, safety, and reliability of reduction techniques are limited. In a recent randomized study, a variation of the Milch technique called FARES (*FA*st, *RE*liable, and *S*afe) was found to be more effective, faster, and less painful than the traction-countertraction and Kocher methods. FARES adds oscillation in a vertical direction while the affected arm is abducted. In this study, reductions were performed by junior residents without any anesthesia, sedation, or analgesia.[39]

The neurovascular examination should ideally be repeated and findings recorded after any attempt at reduction.

Traditional teaching has been to obtain prereduction and postreduction radiographs. Shuster and colleagues investigated the need for prereduction radiographs.[41] In one study, they found that when the emergency physician was clinically confident of the diagnosis, the radiographs were 100% accurate.[41] In a follow-up study, the researchers demonstrated that implementation of voluntary guidelines based on physician certainty allowed for the elimination of prereduction radiographs in 88.9% of cases.[42] It also is generally recommended that radiographic studies be performed after reduction to confirm reduction and identify any associated fractures. Some studies have questioned the need for and cost-effectiveness of routine postreduction radiographs.[43,44] These investigators did not find any new clinically significant fractures on postreduction radiographs and argued that in most instances

www.ketabpezeshki.com 66485457-66963820

a successful reduction can be determined clinically by the presence of a palpable clunk, decrease in pain, and improvement in the range of motion. Reduction in the number of postreduction radiographs also decreases costs and shortens the ED throughput times.[44] The findings on most of these studies are very subjective, however, and one cannot assume that all practitioners will have the same clinical acumen. Other studies show that as many as 7.5% of fractures initially were detected only on postreduction films.[45] Plain radiography of the shoulder is readily available and presents little or no risk to the patient. Unfortunately, failure to confirm reduction with radiographs and failure to diagnose all associated fractures could lead to malpractice claims. For these reasons, imaging of suspected shoulder dislocations remains advisable in most cases, with the possible exception of some patients with a history of recurrent dislocations in the absence of trauma. In these cases, prereduction films may not be necessary; however, a postreduction film may be advisable. In addition, imaging can also identify Bankart's lesions (avulsion of the anteroinferior glenohumeral ligament with capsulolabral detachment), which are an indication for surgery, as well as Hill-Sachs deformities, which when large can be associated with subsequent shoulder instability.

After reduction, the affected extremity is immobilized with a sling and swathe bandage or a Velpeau sling (see Fig. 53-11). Patients should be discharged with adequate analgesia and appropriate follow-up referral. Primary dislocations and complicated cases (associated fracture, rotator cuff tear, axillary nerve injury) should receive orthopedic follow-up care. Conventionally, the shoulder is immobilized for 3 to 6 weeks in younger patients and for 1 to 2 weeks in those older than 40 years.[9] A recent meta-analysis, however, found no added benefit from more prolonged immobilization in younger populations.[46]

The traditional position of immobilization is with the shoulder in internal rotation. Studies suggest that this positioning may delay healing and is associated with a higher recurrence rate.[47] External rotation may allow for better alignment of injured soft tissues (Fig. 53-32). In a randomized clinical trial with a minimum follow-up of 2 years, Itoi and colleagues[48] found that 3 weeks of immobilization in 10 degrees of external rotation was associated with a 26% recurrence rate, compared with a 42% recurrence rate with sling immobilization in internal rotation. Similar findings were reported in a recent systematic review of the literature on immobilization position.[46] Other investigators, however, have failed to confirm this finding, and so the optimal postreduction immobilization position remains unclear.[49] Early initiation of shoulder exercises (see Fig. 53-14) helps reduce the risk of adhesive capsulitis. A meticulous rehabilitation program aimed at restoring the static and dynamic stabilizers of the glenohumeral joint follows the period of immobilization.[9]

Complications. Complications include the aforementioned fractures and neurovascular injuries. Most axillary nerve injuries are neurapraxic, management is expectant, and the prognosis for recovery of function is good.[36] Rotator cuff tears may be present in 10 to 15% of cases.[50] Rotator cuff tears are especially common in primary dislocations in patients older than 40 years. In this setting, failure to abduct the arm often is misdiagnosed initially as an axillary nerve injury. Most of these patients require tendon and capsular repair to restore shoulder stability.[50] Recurrence also is a common complication after anterior dislocation, and patients younger than 30 years have a reported recurrence rate of 79 to 100%. A Hill-Sachs deformity, Bankart's lesion, or a glenoid rim fracture are all associated with increased risk of recurrence.[9] Recent studies suggest that the traditional method of treatment (immobilization followed by physical therapy) is ineffective in preventing redislocation in young, highly athletic persons. Arthroscopic studies of primary anterior dislocations in such patients have detected a high incidence of anterior-inferior capsulolabral avulsions (Bankart's lesion) from the glenoid rim. This avulsion is believed to be the primary predisposing factor for recurrence, and affected patients seem to benefit from early arthroscopic repair of the lesion.[51] Recurrence rates decline with increasing age and in the presence of a greater tuberosity fracture, and possibly immobilization in external rotation.[46,48]

Anterior Subluxation. Transient anterior subluxation of the shoulder is encountered often in young athletic adults. The patient reports sudden sharp shoulder pain and weakness ("dead arm syndrome") that occurred while performing an abduction and external rotation maneuver. The patient also may relate a sensation of the shoulder's slipping in and out. The radiographic appearance usually is normal, and presence of an apprehension sign confirms the diagnosis. For this sign to be elicited, the injury motion (abduction and external rotation of the arm) is gently reproduced while an anterior force is applied to the posterior shoulder (Fig. 53-33). This maneuver increases the pain and may cause anterior displacement of the humeral head. With a positive test result, the patient will actively resist further external rotation and appear apprehensive. A lax or redundant anterior capsule is thought to be responsible for this syndrome, and recurrent episodes are common. These patients should be referred for orthopedic follow-up care because definitive therapy (capsulorrhaphy) is surgical.

www.ketabpezeshki.com 66485457-66963820

Posterior Dislocation

Pathophysiology. Posterior dislocations are rare and account for 2 to 5% of all glenohumeral dislocations.[52] This rarity is explained partly by the anatomy of the shoulder girdle. The 45-degree angulation of the scapula on the thoracic cage positions the glenoid fossa posterior to the humeral head, which serves as a partial buttress against posterior dislocation. More than 50% of posterior dislocations are missed on initial evaluation, and many remain unrecognized ("locked posterior dislocations") for weeks or months.[52,53]

A posterior dislocation can result from several distinct mechanisms of injury. Convulsive seizures (epileptic or after electrical shock) have been associated with unilateral or bilateral posterior dislocations. In this instance, the larger and stronger internal rotator muscles (latissimus dorsi, pectoralis major, teres major, subscapularis) overpower the weaker external rotators (teres minor, infraspinatus) to produce the injury with or without associated trauma.[52] A posterior dislocation also can occur after a fall onto the outstretched hand with the arm held in flexion, adduction, and internal rotation or after a direct blow to the anterior aspect of the shoulder. A seizure disorder should be suspected in cases of unexplained nocturnal posterior dislocations. Acute posterior dislocations are anatomically classified into three types—subacromial (most common), subglenoid, and subspinous—based on the final resting position of the humeral head.[52]

Clinical Features. Early diagnosis is essential to prevent long-term functional and therapeutic complications. As mentioned, the initial examining physician misses the diagnosis with some regularity, in part because of an over-reliance on radiologic findings and an under-reliance on the clinical examination. The most common misdiagnosis is adhesive capsulitis.[52] The patient holds the affected arm across the chest in adduction and internal rotation. Although usually painful, the injury can be relatively painless. The normal shoulder contour is replaced by a flat, squared-off appearance, and the coracoid process is prominent and easily palpated. The humeral head may be palpable posteriorly beneath the acromion process. Abduction is severely limited, and external rotation is completely blocked because the humeral head remains impacted against the posterior glenoid rim.

Diagnostic Strategies: Radiology. True or standard AP radiographs can appear deceptively normal with posterior dislocations. The common difficulty with identifying posterior dislocation in the frontal plane has led to the description of several characteristic radiographic features. Standard AP films show loss of the half-moon elliptic overlap of the humeral head and glenoid fossa. In addition, the distance between the anterior glenoid rim and the articular surface of the humeral head is increased (the rim sign). The humeral head is profiled in internal rotation and takes on a "lightbulb" or "drumstick" appearance (Fig. 53-34). A true AP film shows abnormal overlap of the glenoid fossa with the humeral head (Fig. 53-35). Finally, an impaction fracture of the anteromedial humeral head (reverse Hill-Sachs deformity) is invariably present (see Fig. 53-35). This fracture may produce a curvilinear density on the frontal projection parallel to the articular cortex of the humeral head (the trough sign). An orthogonal view, such as an axillary lateral, transscapular Y (see Fig. 53-34), or apical oblique view, confirms the diagnosis. The axillary lateral view or apical oblique view also identifies associated fractures of the humeral head and posterior glenoid rim. If an adequate orthogonal view cannot be obtained, shoulder CT should be considered.[52,54]

Management. Closed reduction may be attempted in the ED with procedural sedation. The technique of reduction incorporates internal rotation and lateral traction to disimpact the humeral head from the glenoid rim. The humeral head can also be disimpacted with use of the "lever principle"—adducting the arm as much as possible, pulling the forearm in internal rotation to the opposite side of body while simultaneously pushing the medial side of the proximal arm laterally.[55] Once the humeral head is disimpacted, reduction can be accomplished with slow external rotation in conjunction with gentle pressure on the posteriorly displaced head. If this technique fails, reduction with the patient under general anesthesia is indicated. After reduction the shoulder should be immobilized in external rotation with slight abduction.[53] Cases that were missed initially and manifest as chronic or "locked" posterior dislocations should be discussed with the

orthopedist because they often require semielective open reduction and internal fixation or arthroplasty.[53,54]

Complications. Fractures of the glenoid rim, greater tuberosity, lesser tuberosity, and humeral head account for most associated injuries. The subscapularis muscle rarely may be avulsed from its insertion site on the lesser tuberosity. Neurovascular injuries are uncommon because the anterior location of the neurovascular bundle protects it from injury. Recurrent posterior dislocations occur in 30% of patients and predispose the joint to degenerative changes.

Inferior Glenohumeral Dislocation (Luxatio Erecta)

Pathophysiology. Luxatio erecta is a rare type of glenohumeral dislocation in which the superior aspect of the humeral head is forced below the inferior rim of the glenoid fossa. Less than 0.5% of all shoulder dislocations are of this variety, and the mechanism of injury involves either indirect or direct forces.[56] Most inferior dislocations result from indirect forces that hyperabduct the affected extremity. This causes impingement of the humeral head against the acromion process. Further levering of the humeral shaft against the acromion ruptures the capsule and dislocates the head inferiorly (Fig. 53-36). Application of a direct axial load to an abducted shoulder also can disrupt the weak inferior glenohumeral ligament and drive the humeral head downward.

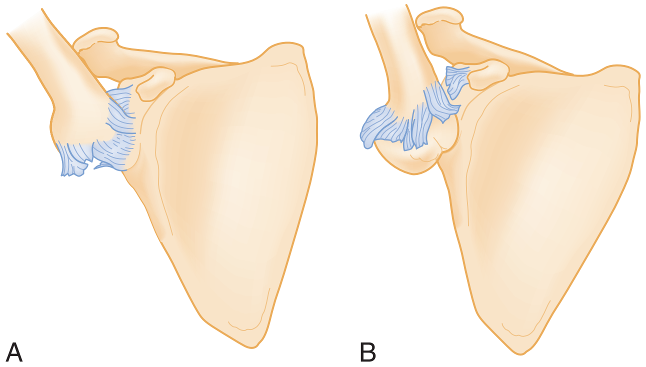

Figure 53-36. Luxatio erecta. **A,** The mechanism by which this injury occurs in hyperabduction. **B,** This is always accompanied by disruption of the rotator cuff and tear through the inferior capsule. (From Simon RR, Koenigsknecht SJ: Emergency Orthopedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

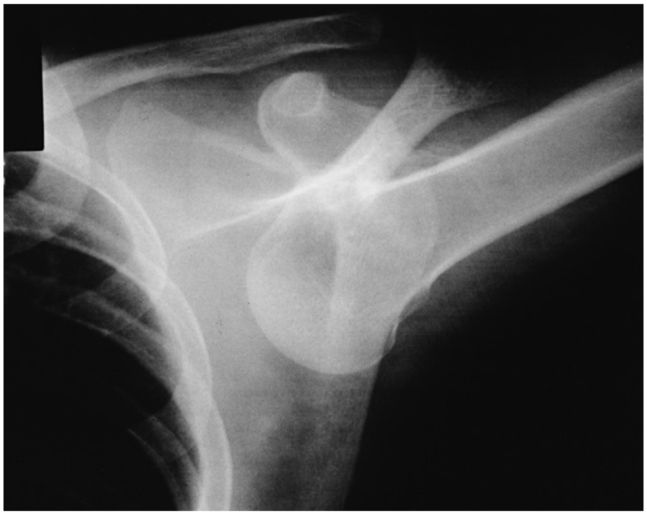

Figure 53-37. Anteroposterior radiographic view of an inferior glenohumeral dislocation. The humeral shaft lies parallel to the spine of the scapula.

Clinical Features. Clinically, the patient has the arm locked overhead in 110 to 160 degrees of abduction. The elbow usually is flexed, and the forearm typically rests on top of the head. The shoulder is fixed in this position, and any attempts at movement result in significant pain. The inferiorly displaced humeral head may be palpable along the lateral chest wall. A thorough neurovascular examination is essential to evaluate for associated injuries.

Diagnostic Strategies: Radiology. Many cases of luxatio erecta are mistakenly diagnosed and treated as subglenoid anterior dislocations because the radiographic features of these two clinical entities are remarkably similar. Standard AP radiographs show the superior articular surface inferior to the glenoid fossa (Fig. 53-37). In addition, the humeral shaft characteristically lies parallel to the

www.ketabpezeshki.com 66485457-66963820

spine of the scapula on the AP view. This radiographic feature is useful in distinguishing luxatio erecta from a subglenoid anterior dislocation: in the latter the humeral shaft lies parallel to the chest wall. Associated fractures of the acromion, coracoid, clavicle, greater tuberosity, humeral head, and glenoid rim are common.

Management. Reduction usually can be accomplished by traction-countertraction maneuvers under procedural sedation. The operator applies traction in line with the humeral shaft while an assistant applies countertraction across the shoulder (Fig. 53-38). Gentle abduction usually reduces the dislocation, and the arm is brought down into an adducted position. Multiple attempts may be necessary; occasionally, "buttonholing" of the capsule will prevent closed reduction, necessitating an orthopedic consultation for open reduction. An alternative approach is the two-step closed reduction maneuver, in which the inferior dislocation is first converted into an anterior dislocation before being reduced.[57] Initially, one hand is placed on the shaft of the dislocated humerus and the other hand on its medial condyle. The hand on the shaft initiates an anteriorly directed force rotating the humeral head from an inferior to an anterior position. The adducted humerus can then be externally rotated to reduce the head into the glenoid fossa. The reported advantages of the two-step maneuver are that it requires a single operator, fewer attempts, minimal force, and only local analgesia or minimal procedural sedation.[57]

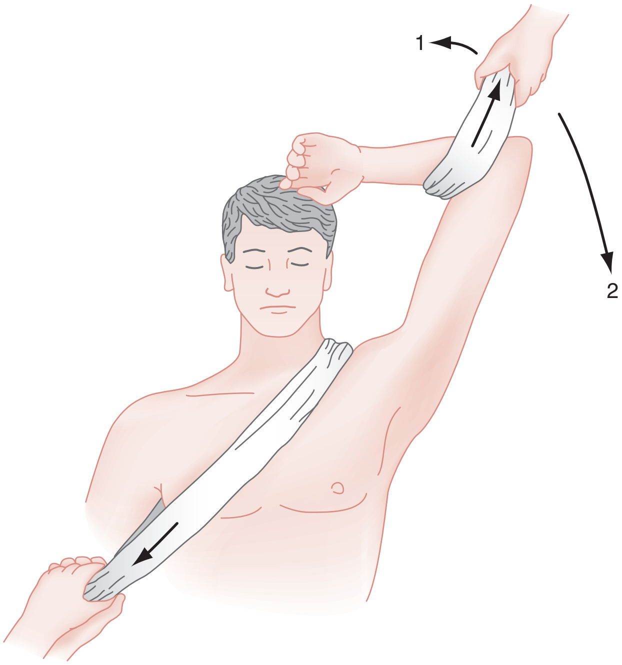

Figure 53-38. Traction-countertraction method for reduction of luxatio erecta humeri. Arrows indicate direction of applied force and relevant movement. The initial maneuver *(1)* includes steady axial traction in line with the humeral shaft position, followed by gentle abduction. This reduces the glenohumeral dislocation. At this point *(2),* the arm is brought down to a position of adduction and internal rotation. (Redrawn from Davids JR, Talbott RD: Luxatio erecta humeri. A case report. Clin Orthop Relat Res 252:144, 1990.)

Complications. Neurapraxic lesions of the brachial plexus are common, and thrombosis of the axillary artery has also been associated with luxatio erecta.[56] Other associated injuries include tears of the rotator cuff, damage to the glenoid labrum, and avulsion fractures of the greater tuberosity.

Scapulothoracic Dislocation

Scapulothoracic dissociation is a rare and severe injury characterized by complete disruption of the scapulothoracic articulation and may be thought of as a partial or complete internal forequarter amputation.[58] The mechanism of injury involves a massive blunt force directed over the shoulder or severe traction force applied to the upper extremity. Approximately 50% of the reported cases involve motorcycle accidents, with the injury occurring when the motorcyclist hangs onto the handlebars while the body is forced away.[59] The diagnosis is based on history, clinical findings, and radiologic studies. The injury often is overlooked at first, because most patients have multiple injuries that distract the treating physician.[59] Massive local soft tissue swelling of the shoulder, along with more than 1 cm of lateral displacement of the scapula on the AP chest radiograph, is pathognomonic for scapulothoracic dissociation (Fig. 53-39). Associated osseous injuries include acromioclavicular separation, displaced fractures of the clavicle, and dislocations of the SCJ. Vascular lesions have been reported in 88% of patients and severe neurologic injuries in 94%, so a thorough assessment for these injuries is essential.[58] Acute limb ischemia is rare because of the extensive collateral network in the shoulder. Vascular and neurologic injuries can be confirmed through angiography and MRI. Outcomes generally are poor, with death in 10% of cases and a flail anesthetic upper extremity in complete brachial plexus injuries. Many of these latter cases eventuate in upper extremity amputation.[58]

Soft Tissue Conditions

Impingement Syndromes: Rotator Cuff Tendinitis, Subacromial Bursitis

Pathophysiology. Rotator cuff tendinitis and subacromial bursitis can be considered part of a pathophysiologic continuum whose

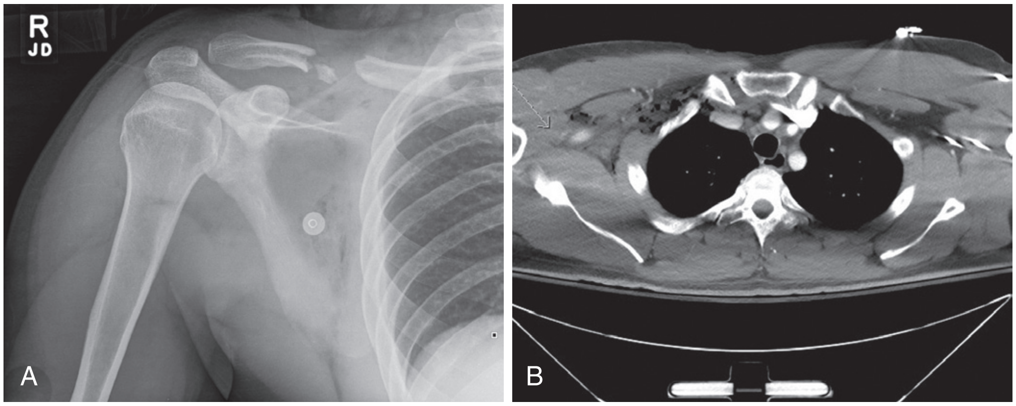

Figure 53-39. Scapulothoracic dissociation with associated clavicle fracture **(A)**, and CT scan of associated axillary artery injury **(B)**.

www.ketabpezeshki.com 66485457-66963820

endpoint is represented by complete rupture of the rotator cuff. These two conditions are common causes of shoulder pain and have similar clinical presentations.[60] A key clinical feature is the presence of a painful arc sign (Fig. 53-40).

The subacromial space is the area between the coracoacromial arch and the greater tuberosity of the humerus. This space, which is only a few millimeters wide, contains the long head of the biceps, the rotator cuff, and the subacromial bursa. The bursa provides the gliding mechanism between the musculotendinous cuff and the coracoacromial arch. The functional arc of shoulder elevation is forward, which normally leads to impingement of the cuff and bursa under the anterior third of the coracoacromial arch. Similar impingement also occurs at 60 to 120 degrees of abduction and with the extremes of adduction. The critical wear from impingement is centered on the supraspinatus tendon, near its insertion on the greater tuberosity. Micro-opaque injection studies also have shown a relative avascularity within this "critical" area. The hypovascularity, in conjunction with repeated wear and age-related degenerative changes, ultimately results in rotator cuff tendinitis. Narrowing of the subacromial space (anatomic variants of anterior acromion) and occupations that require excessive overhead activity accelerate the entire process. With time, the inflammatory reaction spreads to involve the adjacent bursa. This inflammation leads to edema, thickening, and fibrosis, further narrowing the subacromial space (secondary impingement); this is eventually followed by attritional changes within the rotator cuff. Because the rotator cuff is a primary humeral head depressor, loss of function adds to the secondary impingement process.[60]

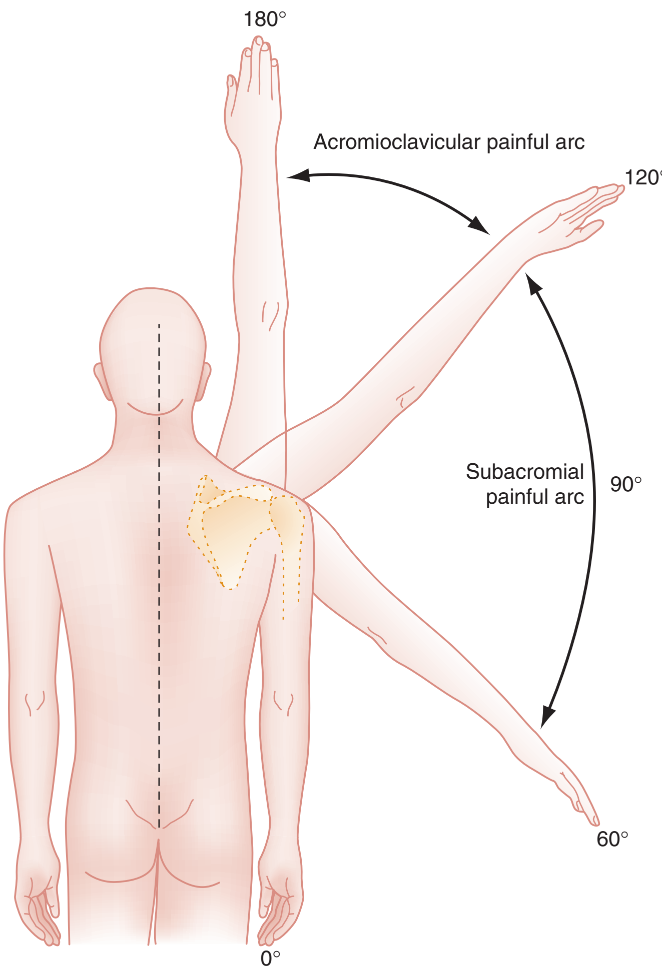

Figure 53-40. Arcs of painful abduction: subacromial painful arc, 60 to 120 degrees; acromioclavicular painful arc, 120 to 180 degrees. (From DePalma AF: Surgery of the Shoulder, 3rd ed. Philadelphia, JB Lippincott, 1983.)

The impingement process also may involve the long head of the biceps. In such cases, bicipital tendinitis, degeneration, or rupture may be present. If osteoarthritis of the ACJ has narrowed the subacromial space, the pathologic process can be accelerated. Impingement in this context occurs at 120 to 180 degrees of abduction (see Fig. 53-40).

Clinical Features. The spectrum of illness is marked by a progression of symptoms.[31] Neer classified the progressive pathologic processes into three stages (Table 53-2).[61] Patients in stage 1 report a dull ache around the deltoid area after strenuous activity. On examination, tenderness can be elicited over the supraspinatus and anterior acromion. A painful arc of abduction at 60 to 120 degrees is characteristic. The Neer impingement sign (Fig. 53-41) has a sensitivity of 68% for all three stages. Several other tests have been described for the diagnosis of impingement syndrome. The combination of the Hawkins-Kennedy impingement sign (arm placed into 90 degrees of flexion followed by internal rotation), the painful arc sign, and the infraspinatus muscle test (resistance to internal rotation with arm adducted and elbow flexed to 90 degrees) provided the best post-test probability (95%) in one large clinical study.[62]

Stage 2 is characterized by more persistent pain that is particularly severe at night. The inflammatory process within the bursa and tendons leads to the formation of minor adhesions. Disruption of these adhesions is thought to account for the nighttime pain. Physical findings are similar to those in stage 1. In addition, bursal thickening leads to increased soft tissue crepitus within the glenohumeral joint.

The hallmark of stage 3 is significant tendon degeneration after a prolonged history of tendinitis and bursitis. Findings in this stage are discussed in the subsequent section on tears of the rotator cuff. The radiographic appearance usually is normal in stages 1 and 2. Findings in stage 3 are similar to those with complete tears of the rotator cuff.

The differential diagnosis of impingement syndrome is extensive and includes intrinsic and extrinsic causes of shoulder pain. Extrinsic sources include the cervical spine, lung, heart, and diaphragm. Intrinsic conditions include acromioclavicular arthritis, adhesive capsulitis, calcific tendinitis, and traumatic anterior subluxation. A Neer impingement sign may be present in many of these other conditions. Relief of pain after the subacromial injection of 10 mL of 1% lidocaine (impingement test; see Fig. 53-41) helps localize the condition to the subacromial space.

Table 53-2 Three Progressive Stages of Impingement Lesions

STAGE	PATHOLOGIC FINDINGS	AGE (yr)	COURSE	TREATMENT
1	Edema, hemorrhage	<25	Reversible	Conservative
2	Fibrosis, tendinitis	25-40	Recurrent pain with activity	Conservative, surgical
3	Bone spurs, tendon rupture	>40	Progressive disability	Surgical

www.ketabpezeshki.com 66485457-66963820

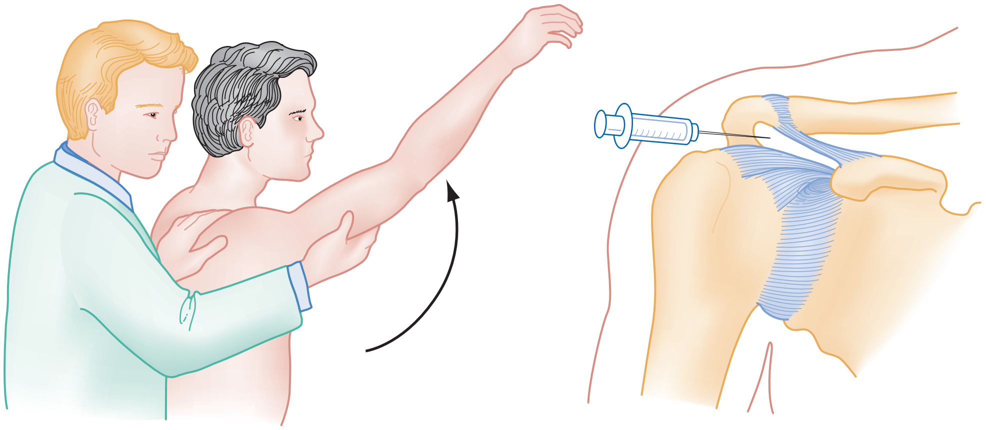

Figure 53-41. Impingement injection test. The impingement sign is elicited with the patient seated or standing and the examiner standing. Scapular rotation is prevented with one hand while the other hand raises the arm in forced forward elevation *(arrow),* causing the greater tuberosity to impinge against the acromion. This maneuver produces pain in patients with impingement lesions of all stages. It also causes pain in many other shoulder conditions. In the case of impingement lesions, the pain caused by this maneuver is relieved by the injection of 10 mL of 1% lidocaine beneath the anterior acromion. This test is useful in separating impingement lesions of all stages from other causes of shoulder pain. (Redrawn from Neer CS 2nd: Impingement lesions. Clin Orthop 173:70, 1983.)

Table 53-3 Potency, Duration of Action, and Recommended Dose of Commonly Used Corticosteroid Preparations

PREPARATION (TRADE NAME)	RELATIVE POTENCY	DURATION OF ACTION	SUBACROMIAL DOSE (mg)
Hydrocortisone acetate (Hydrocortone)	1	Short	25-37.5
Betamethasone sodium phosphate and acetate (Celestone Soluspan)	25	Short/long	6
Methylprednisolone acetate (Depo-Medrol)	5	Long	40-80
Triamcinolone acetonide (Kenalog-10)	5	Long	10-20
Triamcinolone hexacetonide (Aristospan)	5	Long	20
Triamcinolone diacetate (Aristocort)	5	Long	25
Dexamethasone acetate (Decadron-LA)	25	Long	4-16

Management. Initial treatment in stage 1 impingement syndrome is conservative and consists of rest, nonsteroidal anti-inflammatory drugs (NSAIDs), and modification of activities that produce impingement. In stage 2, emphasis is on maintaining flexibility and range of motion through physiotherapy and rotator cuff strengthening exercises. Patients with stage 1 and 2 disease in the ED with reports of treatment failure with NSAIDs may benefit from a subacromial injection of a local anesthetic (lidocaine or bupivacaine) and corticosteroid preparation (Table 53-3), along with referral to a primary care sports medicine physician. Corticosteroid injections take 3 to 4 days to achieve their full effect and need to be injected accurately into the subacromial bursa.[63] Patients with treatment-refractory stage 2 and stage 3 disease may require decompression surgery to control pain. Patients with stage 2 and stage 3 disease may benefit from referral to an orthopedist for more detailed evaluation and treatment.

Rotator Cuff Tears

Pathophysiology. The rotator cuff acts as a dynamic stabilizer of the glenohumeral joint. Its primary function is to hold the humeral head in place throughout the full range of motion (see Fig. 53-5). In addition, it contributes power in all directions and is responsible for specific movements. The infraspinatus and teres minor act as external rotators, whereas the subscapularis is an internal rotator. The supraspinatus is essential for the first 30 degrees of shoulder abduction.

The tenuous blood supply of the rotator cuff, abusive tensile overload, and chronic wear under the coracoacromial arch predispose it to age-related degenerative changes. The advanced stage of this process is characterized by complete rupture of the rotator cuff.

The role of impingement in the development of rotator cuff tears is controversial. Primary impingement (e.g., impingement related to variation in acromion anatomy) is uncommon but when present accelerates the degenerative process. More often, weakening or rupture of the cuff with age allows for superior migration of the humeral head, which results in secondary impingement. This impingement produces secondary changes within the subacromial space and symptoms characteristic of the impingement syndrome.

Rotator cuff tears typically involve the dominant arm and occur in men older than 40 years. The occupational history is significant for strenuous work requiring overhead activity. Most tears occur near the attachment of the supraspinatus and can extend anteriorly into the subscapularis or posteriorly into the infraspinatus. Tears can be classified according to their size, completeness, pattern location, or duration. A clinically useful system is to divide tears into acute or chronic types. Acute tears (10%) usually are associated with a specific traumatic event. Often, no history of previous shoulder problems can be identified. The most common mechanism of injury is forced abduction associated with significant resistance; this usually occurs when the patient attempts to break a fall with an outstretched hand. Alternatively, the tendon

www.ketabpezeshki.com 66485457-66963820

rupture may occur with attempts to lift a heavy object or with a fall directly onto an immovable object.[64]

Clinical Features. With acute tears, patients typically report a sudden tearing sensation in the shoulder followed by severe pain that radiates into the arm. Pain and secondary muscle spasm limit shoulder motion. Physical findings depend on the completeness, size, and location of the tear. Point tenderness is usually present over the site of rupture (greater tuberosity). A palpable defect also may be present. Subacromial injection of 10 mL of 1% lidocaine eliminates pain and allows for proper evaluation of motor function. The patient with a large tear cannot initiate shoulder abduction. A discrepancy between active and passive range of motion is highly suggestive of a rotator cuff tear.[64] The drop-arm test, performed by passively abducting the arm to 90 degrees and asking the patient to hold the arm in this position, is positive with significant tears. Slight pressure on the distal forearm or wrist causes the patient to drop the arm suddenly. The acute pain resulting from hemorrhage and spasm subsides over a few days. Repeat examination at this point confirms the loss of function in significant tears.

Chronic tears account for approximately 90% of all lesions. Chronic tears are attritional and more insidious in their presentation. Early findings include the painful arc sign as a result of secondary impingement. The pain is worse at night and interferes with sleep. Worsening pain is followed by the gradual onset of weakness in the arm. Flexion and abduction are affected first. The patient attempts to initiate abduction with scapulothoracic movement. Internal rotation is weakened by anterior extension of the tear. Posterior extension compromises external rotation. The drop-arm test result is positive with large tears, and atrophy of the supraspinatus and infraspinatus muscles may be seen. In a large clinical study, the combination of the painful arc sign, positive drop-arm test result, and positive infraspinatus muscle test result produced the best post-test probability (91%) for full-thickness rotator cuff tears.[62]

Diagnostic Strategies: Radiology. Radiographs may be normal in acute and chronic tears, but more often they show evidence of nonspecific degenerative changes within the glenohumeral joint and subacromial space. The greater tuberosity can have a sclerotic or cystic appearance. Osteophytic spurs and sclerosis of the undersurface of the acromion may narrow the subacromial space. The hallmark of a complete tear is superior displacement of the humeral head. This displacement is best seen on an external rotation view. The normal distance from the superior aspect of the humerus to the undersurface of the acromion ranges from 7 to 14 mm. A distance of less than 6 mm is highly suggestive of a complete tear. Outpatient ultrasound examination, MRI, or an arthrogram can confirm the diagnosis. Ultrasound appears to be an excellent initial screening test, and in one study the overall accuracy of ultrasonography in the detection of partial- and full-thickness rotator cuff tears was 87%, with arthroscopy used as the "gold standard" diagnostic modality.[65]

Management. Acute tears should be immobilized in a sling and the patient referred promptly for orthopedic follow-up care. Early surgical repair (before 3 weeks) is preferred in these instances, especially for a young or active person. The management of chronic tears includes pain control and a shoulder rehabilitation program. Painful arc symptoms may respond to subacromial injection of a corticosteroid (see Table 53-3). Orthopedic follow-up care is essential because patients with persistent pain and weakness may require surgical repair.

Lesions of the Biceps Muscle

The biceps is composed of two heads. The long head originates from the supraglenoid tubercle and glenoid labrum and ascends over the humeral head to enter the arm by way of the bicipital groove. The long head is covered by a synovial sheath and is held in place within the groove by the coracohumeral and transverse humeral ligaments. The short head of the biceps originates from the coracoid process and inserts with the long head onto the tuberosity of the radius. The biceps is responsible for flexion as well as supination at the elbow and serves as a stabilizer for the glenohumeral joint.

Bicipital Tendinitis

Pathophysiology. Anatomically, the long head of the biceps is subject to the same stresses as those incurred by the rotator cuff within the subacromial space. Irritation and microtrauma as a result of repetitive elevation or abduction of the shoulder produce an inflammatory reaction within the synovial sheath. Bicipital tendinitis usually is associated with other acromial arch impingement conditions (e.g., subacromial bursitis, rotator cuff tendinitis).[66]

The typical patient is middle-aged and involved in an occupation or recreational activity that requires overhead movement. The presenting complaint is pain in the anterior part of the shoulder along the bicipital groove that radiates into the upper arm. There is usually no history of trauma. Pain increases with activity and decreases with rest. Abduction and external rotation in particular are painful. Pain is worse at night and may interfere with sleep.

Primary bicipital tendinitis (inflammation without other underlying pathology) is rare (5% of cases) and affects younger individuals.[66]

Clinical Features. On examination, point tenderness can be elicited over the biceps tendon as it passes through the bicipital groove. This is best shown with the arm in 10 degrees of internal rotation. Active range of motion is limited by pain, but the passive range remains intact. Supination against resistance—the Yergason test—with the arm adducted and the elbow flexed to 90 degrees reproduces the pain in 50% of cases (Fig. 53-42).[66] Another proactive test is the biceps resistance test (Speed test), in which forward flexion of the shoulder (elbow extended and forearm supinated) carried out against resistance produces pain in the bicipital groove. The specificity of these tests is limited in the presence of impingement and rotator cuff disease.

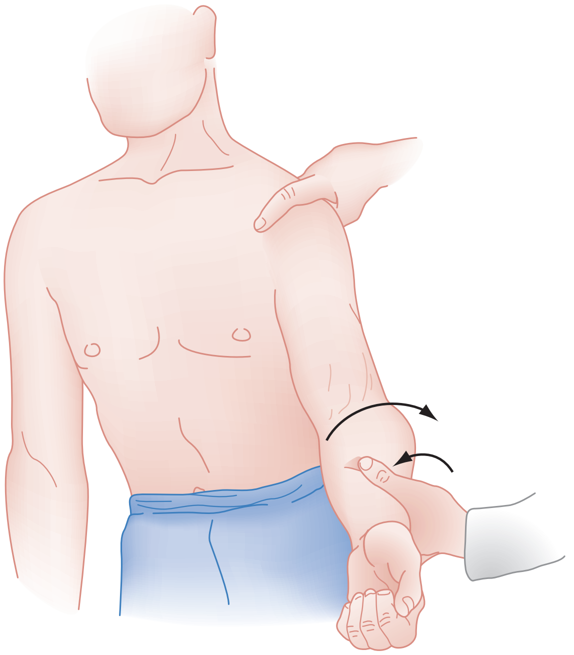

Figure 53-42. Yergason's test. With the elbow flexed, supination of the forearm *(arrows)* against resistance causes pain in the anterior and inner aspect of the shoulder. (From DePalma AF: Surgery of the Shoulder, 3rd ed. Philadelphia, JB Lippincott, 1983.)

www.ketabpezeshki.com 66485457-66963820

Diagnostic Strategies: Radiology. Radiographs are usually normal but may show evidence of subacromial space impingement by associated acromioclavicular arthritis and osteophytic spurs. The preferred imaging modality is MRI.[67]

Management. Emergency treatment consists of rest (immobilization in a sling), application of ice, and an NSAID regimen. Gentle stretching exercises are encouraged as symptoms subside. Refractory or progressive cases should be referred to an orthopedic surgeon. Although the bicipital sheath can be injected with a corticosteroid preparation, the procedure is technically difficult, and inadvertent direct tendon injection can lead to tendon rupture. An alternative option is iontophoresis with a topical steroid over the bicipital groove.[67] Surgery may be necessary in patients who fail to respond to conservative therapy.

Ruptures of the Biceps Tendon

Pathophysiology. Ruptures of the biceps tendon can be classified into proximal and distal types. Distal ruptures are rare and are not discussed here. Proximally, microtears and other age-related attritional changes within the long head predispose it to rupture.[64] The rupture can be spontaneous or may follow a traumatic event involving either forced extension or resisted supination and flexion.

Clinical Features. The classic history of an acute rupture is that of a sudden snap or pop, followed by pain and ecchymosis along the arm. The tendon usually ruptures at its weakest point, which is just distal to the exit from the glenohumeral joint cavity. With a complete rupture, distal retraction of the muscle results in a "Popeye" appearance of the arm. A difference in muscle contour (Ludington sign) also may be seen when both arms are placed behind the head and the biceps muscles are contracted. Functionally, forearm supination is weakened, but elbow flexion stays strong because the coracobrachialis and short head of the biceps remain intact. Most bicep tendon ruptures are associated with the impingement syndrome and a rotator cuff tear.

Diagnostic Strategies: Radiology. Radiographic findings usually are unremarkable, and the confirmatory test of choice is MRI.

Management. The injured arm should be immobilized in a sling with the elbow in 90 degrees of flexion. The local application of ice may provide temporary relief. Analgesia should be provided, and the patient should be referred to an orthopedic surgeon for further evaluation and treatment within 72 hours. Surgical repair is a consideration in young, active persons. In older patients, conservative therapy (range-of-motion and strengthening exercise) is preferred because the cosmetic deformity is minimal and the mild functional loss usually is acceptable.

Subluxations and Dislocations of the Biceps Tendon. Subluxations and dislocations of the biceps tendon usually are associated with a congenitally shallow bicipital groove or atraumatic (attritional) tears of the coracohumeral and transverse humeral ligaments. The patient reports a snapping sensation in the upper arm with abduction and external rotation. External and internal rotation of the abducted shoulder shows dislocation and relocation of the tendon. With complete dislocation, the arm may reflexively drop to relocate the tendon. These conditions may require operative repair and should be referred to an orthopedist.

Calcific Tendinitis

Pathophysiology. Shoulder calcific tendinitis affects up to 10% of the population and frequently is encountered in the ED. The condition affects people aged 30 to 50 years and is painful in 50% of patients.[68] Calcific deposits occur primarily in the supraspinatus tendon near its attachment to the greater tuberosity. Deposits also may involve the infraspinatus, teres minor, or subscapularis tendons. Women are more often affected than men, and 10% of the patients have bilateral deposits. In the precalcific stage, the tendon undergoes fibrocartilaginous transformation. The precipitating factors for this change remain unclear and may involve hypoxia- or stress-related degenerative changes within the tendon.[69] Calcium hydroxyapatite crystals are deposited and coalesce within the matrix of the tendon. Subsequent invasion of vascular channels into the deposit allows for the influx of neutrophils and macrophages (inflammatory response), which remove the calcification through phagocytosis. Finally, fibroblasts form collagen to create a postcalcification scar.[69]

Clinical Features. The clinical presentation can be divided into silent, subacute, and acute phases based on the physical characteristics of the calcific deposits and the nature of the inflammatory response within the tendon and subacromial bursa. The silent phase consists of a dry, powdery deposit with no surrounding inflammatory reaction. It usually is an incidental diagnosis when shoulder radiographs are obtained for other purposes. The deposits may remain painless and eventually reabsorb.

The painful arc syndrome is a hallmark of the subacute phase of calcific tendinitis. Enlargement and softening of the deposit lead to narrowing of the subacromial space, resulting in impingement under the acromial arch. Pain experienced at 60 to 120 degrees of abduction (see Fig. 53-40) is characteristic.

A severe inflammatory reaction within and around the deposit produces the acute phase of calcific tendinitis. The deposit becomes milky and has the appearance of an acute abscess. The patient is in severe pain and holds the arm close to the chest. Active and passive range of motion is severely limited. The shoulder is warm and extremely tender to the touch. Severe pain is related to increased intratendinous pressure, and spontaneous rupture of the deposit into the subacromial bursa can be associated with dramatic relief of symptoms.

Diagnostic Strategies: Radiology. Radiographs show calcific deposits in the involved tendon (Fig. 53-43). For the supraspinatus, calcific deposits are best seen on the internal and external rotation AP views. The axillary view is useful for showing calcification within the other tendons of the rotator cuff.

Management. Subacute symptoms usually respond to NSAIDs and measures to limit any offending activity. The acute phase should be treated with sling immobilization, NSAIDs, and analgesia. Subacromial injection of a local anesthetic may provide dramatic temporary relief in the ED. Needle lavage (puncturing of the calcific deposits to decrease intratendinous pressure) under ultrasound or fluoroscopy guidance also has been described as an effective treatment during the acute phase.[69] The subacromial injection of corticosteroids for impingement symptoms is controversial because these agents may delay the process of calcium resorption, thereby interfering with the natural course of the condition. Patients with chronic symptoms may benefit from surgical removal or extracorporeal shock wave therapy to produce

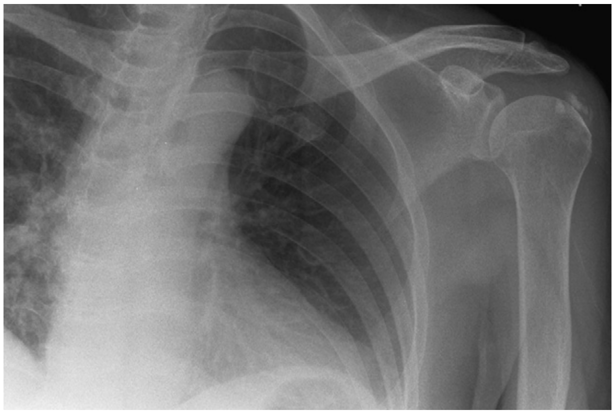

Figure 53-43. Rotator cuff calcific tendinitis.

www.ketabpezeshki.com 66485457-66963820

fragmentation of the calcific deposits.[68,69] Early shoulder range-of-motion exercises should be encouraged in all patients to minimize the risk of adhesive capsulitis. All symptomatic patients should be referred for orthopedic follow-up care.

Adhesive Capsulitis

Pathophysiology. Adhesive capsulitis ("frozen shoulder") is a specific diagnostic entity characterized by an idiopathic inflammatory reaction within the capsule and synovium of the glenohumeral joint. The inflammatory reaction results in the formation of adhesions within the capsule and inferior axillary fold, leading to restricted active and passive range of motion. The prevalence rate is 2 to 5%, with a female predominance.[70] Adhesive capsulitis is more common in diabetic patients. Adhesive capsulitis should be differentiated from other, more common causes of the painful stiff shoulder; this distinction is important because any painful condition of the shoulder (e.g., calcific tendinitis, rotator cuff tear, osteoarthritis, or trauma) may be associated with decreased range of motion.[70] Although the cause of adhesive capsulitis remains unknown, any condition associated with prolonged disuse of the arm can result in capsular contraction, including voluntary immobilization after calcific tendinitis, rotator cuff injury, mastectomy, or a distal upper extremity injury (Colles' fracture).

Clinical Features. The typical patient is a diabetic woman 40 to 60 years of age. The nondominant arm usually is affected, and the patient has trouble with the activities of daily living. The pain often is severe at night and localized over the deltoid area. As the condition progresses, there is uniform limitation of all glenohumeral movement, including flexion, abduction, and rotation. On passive testing, a sense of mechanical restriction of joint motion can often be appreciated. Shoulder radiographs usually are normal in appearance if no associated pathologic condition is present.

Management. The best form of therapy is preventive in nature. Prolonged shoulder immobilization is avoided, and early motion is encouraged in all instances (see Fig. 53-14). Treatment of adhesive capsulitis in the ED consists of NSAIDs and referral to an orthopedic surgeon. Initial therapy usually is conservative and consists of a gentle assisted exercise program along with intra-articular steroid injection. Surgical treatment, including manipulation under anesthesia and arthroscopic capsular release, is reserved for patients in whom nonoperative treatment for at least 6 months has failed to produce improvement.[70]

Injection Therapy. The local injection of corticosteroid preparations can be useful in many painful conditions that affect the shoulder, including rotator cuff tendinitis and subacromial bursitis. Evidence-based research that supports or refutes the use of injection corticosteroid therapy is limited and conflicting.[71] Potential explanations for discordant results of randomized controlled studies include differing outcome definitions and the observation that subacromial injections are difficult to give.[72] The accuracy of needle placement for subacromial injections has been reported to be 70%.[63] Although useful for relieving the inflammatory reaction, corticosteroid injections in general do not alter the underlying disease process. Corticosteroids inhibit all phases of the inflammatory response, including leukocyte migration, edema formation, mediator release, vascular permeability, collagen deposition, and fibroblast proliferation. Systemic complications are rare after local injection therapy. Site-specific complications include articular cartilage damage, tendon weakening or rupture, and subcutaneous atrophy. The incidence of local complications correlates with the injection technique, dose used, and frequency of administration. Direct tendon injection is avoided at all times, and the number of steroid injections should be limited to two per shoulder since a high failure rate for rotator cuff repairs has been reported in patients who have received more than three preoperative subacromial injections.[63]

Numerous corticosteroid preparations are available (see Table 53-3). Injection of a long-acting agent or a combination of a short-acting and a long-acting agent is preferred. The dose used depends on the size of the joint or bursa and the response of the individual patient. With concurrent use of a local anesthetic agent for acute pain relief, better diffusion of the steroid preparation may be obtained.

After injection, the shoulder should be immobilized and activity should be limited for several days to protect against further injury. Improvement usually begins within 1 to 7 days and can last weeks to months, depending on the preparation and underlying condition. Local anesthetic injection may result in dramatic temporary relief of symptoms in the ED.

KEY CONCEPTS

- A thorough neurovascular examination is essential and is performed before and repeated after any manipulation.
- Axillary nerve function is best evaluated by testing the motor function of the deltoid muscle.
- The three-view trauma series of the shoulder (true AP, scapular Y, and axillary views) leads to an accurate radiographic diagnosis of most fractures and dislocations, although specialized views are necessary in some instances. The presence of unfused epiphyses in adolescents and young adults is an important consideration, and comparison films may be indicated on a selective basis.
- Most fractures can be treated conservatively with good functional outcomes.
- The most important aspect of scapular fractures is the high incidence of associated injuries to the ipsilateral lung, chest wall, and shoulder girdle complex.
- Posterior SCJ dislocations can be associated with life-threatening injuries within the superior mediastinum, which are best visualized with a chest CT angiogram.
- If the coracoclavicular distance exceeds 10 to 13 mm, or if a difference of more than 5 mm in this distance is observed between the injured and the uninjured sides, a grade III ACJ dislocation should be suspected.
- Most studies have concluded that conservative treatment of type III ACJ dislocations achieves functional results equal to or in some cases better than those achieved with surgical intervention.
- A compression fracture of the posterolateral aspect of the humeral head (Hill-Sachs deformity) is present in a large percentage of anterior glenohumeral dislocations.
- Recurrence is a common complication after anterior dislocation, especially in male patients younger than 30 years, and such patients may benefit from surgical repair.
- Posterior dislocation should be included in the differential diagnosis of any shoulder injury. A posterior dislocation should be suspected in any patient who reports shoulder pain or discomfort after a convulsive episode and in the presence of a lesser tuberosity fracture.
- It is important to evaluate the relationship between the spine of the scapula and the longitudinal axis of the humerus to avoid missing an inferior glenohumeral dislocation.
- Early initiation of passive shoulder range-of-motion exercises helps reduce the risk of adhesive capsulitis when the shoulder is immobilized for any reason.
- It is important to be familiar with several techniques for the reduction of anterior shoulder dislocations.

CHAPTER 54

MUSCULOSKELETAL BACK PAIN

Michelle Lin and Bory Kea

LOW BACK PAIN

PERSPECTIVE

Background

Approximately 70 to 90% of adults during their lifetime experience *acute low back pain,* defined as pain lasting less than 6 weeks in duration.[1,2] The cause of the back pain remains unknown in 85% of affected persons after appropriate initial investigation—a situation frustrating for both physician and patient.[3] Frequent diagnoses in such cases include "acute lumbosacral strain," "lumbago," and "mechanical back pain." These nonspecific, catch-all terms reflect the diagnostic challenge and lack of pathognomonic tests for low back pain. More accurately, these patients should be diagnosed with *idiopathic low back pain.* Regardless, most cases resolve spontaneously within 6 weeks. In recent studies on the management of acute low back pain, the most significant discovery—contradictory to traditional teaching from the 1980s—is the need for these patients, including those with sciatica symptoms, to avoid bed rest.[4,5] Management recommendations for chronic back pain remain controversial, however, and the condition accounts for a significant proportion of costs to the health care system.

Epidemiology

In the ambulatory care setting the medical complaint of back pain is the fifth most common reason for a visit to a physician's office, with 15 million annual visits in the United States, of which 7.3 million are to the emergency department (ED) at an average of 20,000 visits per day in 2008.[6,7] Back pain was the leading cause of pain as reported in the 2010 National Health Interview Survey (NHIS), with 28.8% of the respondents reporting back pain lasting at least 1 day within the previous 3 months.[8] Back pain primarily affects adults 30 to 60 years of age and has a tremendous impact on worker productivity, with significant economic consequences. It is the second leading cause of pain resulting in lost productive time from work, following headache.[9] For aggregate hospitalization costs alone, it was the ninth most expensive condition in 2008 at more than $9.5 billion.[7] Overall, patients with back pain account for billions of dollars in total direct and indirect costs in the United States.[1,2,10]

The natural history of most cases of low back pain follows a benign and self-limited course. In a large pooled analysis, patients reported a decrease in back pain by 58% within 1 month. If the pain did not resolve within 3 months, however, it was unlikely to resolve after 12 months. The recurrence rate for pain was 66 to 84% within the first 12 months.[11]

Risk factors for low back pain are continually being investigated. In a large systematic review, the presence of nonorganic signs of pain, poor pain-coping behaviors, great functional impairment, poor general health, and known psychiatric disease seem to predict patients who would develop chronic, disabling back pain in the future.[12] Early evidence also points to a genetic predisposition to lumbar disk disease.[13] Multiple other factors have been investigated, including body habitus, various occupations, deconditioning, tobacco smoking, stress levels, and psychological profile, with conflicting results.[13-19]

PRINCIPLES OF DISEASE

Anatomy and Physiology

The lumbosacral spine consists of five lumbar vertebrae and the sacrum. Moving from anterior to posterior, each vertebra can be divided into the cylindrical vertebral body, two pedicles, two transverse processes, two overarching laminae, and a spinous process. These structures surround the neural canal, which houses the spinal cord and nerve roots and has a midsagittal anteroposterior diameter of 15 to 23 mm. The paired superior and inferior articulating processes join the articulating processes one vertebral level above and below. Each articulation site is called a *facet joint.* Intervertebral disks interpose between vertebral bodies, providing elasticity and stability to the vertebral column. Each disk consists of an inner colloidal gelatinous substance, the *nucleus pulposus,* and an outer capsule, the *annulus fibrosus,* which is thinner posteriorly than anteriorly (Fig. 54-1).

Various ligaments and muscles also provide stability to the lumbosacral spine. The anterior and posterior longitudinal ligaments course along the anterior and posterior surfaces of the vertebral bodies. The posterior longitudinal ligament forms a border between the intervertebral disks and the neural canal. As expected, because this ligament thins as it runs inferiorly from L1 to S1, 95% of lumbar disk herniations occur at the L4-5 and L5-S1 levels, causing pain and neurologic deficit in the L5 and S1 distribution. Most herniations extrude posterolaterally to impinge on a nerve root asymmetrically.[20] The ligamentum flavum courses just anterior to the laminae within the neural canal. With age, this ligament can thicken, potentially causing spinal stenosis.

The spinal cord ends at the L1-2 interspace, and the lower cauda equina nerve roots extend inferiorly, exiting the sacral foramina as peripheral nerves to the lower extremity. Pain fibers supplying structures in the lumbosacral region primarily arise from the posterior rami and sinuvertebral nerves at each lumbar vertebral level. The nucleus pulposus and inner annular fibers of the intervertebral disk are unique in their lack of any pain fibers.[21] This

www.ketabpezeshki.com 66485457-66963820

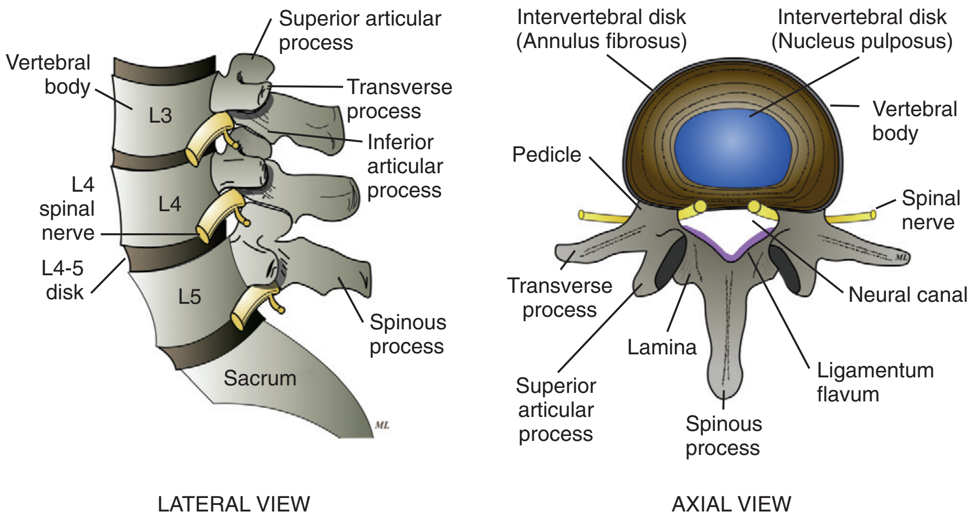

Figure 54-1. Lateral and axial views of lumbar vertebral anatomy.

anatomic feature correlates consistently with magnetic resonance imaging (MRI) evidence of disk pathology in as many as 31% of asymptomatic patients. On follow-up, one study showed that abnormal disk findings in asymptomatic individuals did not predict the future development of back pain after 7 years.[21,22]

Pathophysiology

Most conditions of low back pain have no proven cause. It is estimated that 85% of patients have no definitive diagnosis and are presumed to have pain originating from the soft tissue, including the muscles and ligaments.[10,20] In the other 15% of patients with a known cause, the pain may originate in the nerve root, the articular facets, or the bone itself.

In low back pain of *nerve root origin,* a spinal nerve root can become inflamed and painful with external impingement. Disk herniation, usually at the L4-5 and L5-S1 levels, is the most common cause of *sciatica* (i.e., pain radiating down the posterior leg from sciatic nerve root irritation). As the disk starts to desiccate and degenerate, starting in their 30s, patients are at increased risk for outward herniation of the nucleus pulposus with consequent nerve root impingement. With further aging, these disks progressively shrink in size. In keeping with these findings, symptomatic disk herniations typically are found in patients 30 to 50 years of age. Local nerve ischemia from physical compression also may contribute to the inflammation and pain. Studies also show that exposure of the nucleus pulposus during disk herniation may result in local neural inflammation, leading to pain.[23] Nerve root impingement also can occur with spinal stenosis, a narrowing of the neural canal from congenital narrowing or, more often, from degenerative or hypertrophic changes of the disks, vertebrae, facet joints, and ligamentum flavum.[24]

The two most critical conditions that cause nerve irritation are cauda equina syndrome and a spinal epidural abscess. Cauda equina syndrome is most commonly a result of a massive central disk herniation, usually compressing multiple, bilateral nerve roots and causing back pain radiating to both legs, saddle anesthesia, and impaired bowel and bladder function (i.e., diminished rectal tone and urinary retention, respectively). Emergent surgical decompression is indicated to preserve neurologic function. An epidural abscess similarly results in nerve root impingement, commonly with spinal cord involvement, causing significant back pain and ultimately neurologic deficits. These rare infections develop most commonly from the hematogenous spread of both methicillin-sensitive and methicillin-resistant *Staphylococcus aureus.*[20]

Congenital and developmental spinal abnormalities also may cause back pain by nerve root inflammation in some cases, but much less frequently than was thought previously. Conditions such as kyphosis and scoliosis usually do not cause pain unless the degree of vertebral column misalignment is pronounced.[25] Similarly, spondylolisthesis (slippage of one vertebral body on another) does not usually cause pain if the slippage is less than 25% of the vertebral body width. Even in patients with higher grades of anterior slippage (anterolisthesis), the development of severe back pain is rare. Although it is one third as common as anterolisthesis, backward slippage (retrolisthesis) is almost always associated with back pain. Multifactorial causes of spondylolisthesis include degenerative changes and trauma. Degenerative lumbar spondylolisthesis in older patients occurs most often at the L4-5 level (7.4% overall population prevalence), followed by the L5-S1 level (1.9%) and the L3-4 level (1.7%).[26] Spondylolisthesis often is associated with bilateral pars interarticularis defects in the affected vertebra (spondylolysis).

In low back pain of *articular facet origin,* as with any other joint in the body, degenerative changes in the synovial articular facets in the lumbosacral spine occur with age. Although the exact role and significance of articular facet joints in back pain are unclear, facet pathology has been suggested to contribute to 15 to 45% of chronic back pain cases.[27]

In low back pain *originating from bone,* direct irritation of the vertebral bone and its periosteum can cause back pain. The causes of spondylitis (osteomyelitis of the axial skeleton) can range from a slowly progressing tuberculosis infection (Pott's disease) to a more acute bacterial infection. Typically, bacteria seed the bone from a hematogenous source, such as from a skin wound or urinary tract infection, or directly from intravenous drug use. The most common bacterial culprit is *S. aureus.* Primary and metastatic bone neoplasms can cause back pain from tumor infiltration into the bone. Primary bone tumors, such as multiple myeloma, chordoma, Ewing's sarcoma, and osteosarcoma, occur 25 times less frequently than metastatic disease.[28] Of the neoplasms, breast, lung, prostate, thyroid, and kidney cancers and lymphoma are the most likely to metastasize to bone. Inflammatory conditions, such as ankylosing spondylitis, other arthropathies, and osteoporosis also can cause back pain. In osteoporosis the generalized decrease in bone mineralization can cause pain from microfractures of the vertebral column.

www.ketabpezeshki.com 66485457-66963820

Referred pain, most commonly from intraperitoneal and retroperitoneal abdominal pathology, also is considered in patients with back pain. Chronic back pain is complex and multifactorial. Not only are the structural causes unclear, but the nonphysical factors are variable and difficult to determine. Functional factors range from fear, depression, and personality disorders to financial motivation. Although it is likely that many of these patients do experience some kind of chronic pain, it is unknown why their pain then triggers depression, drug dependence, and malingering in some people but not in others. One difference may be the degree of disruption that the condition causes in the patient's lifestyle. A normally active and athletic person who is incapacitated is more profoundly affected than someone who is habitually sedentary. Psychological factors and potential compensation play a large role in the behavior of many patients with chronic back pain.[12,17,29,30]

It has traditionally been taught that pediatric back pain results in a diagnosis more often than adult pain; however, this axiom has been called into question as multiple studies have shown an increasing number of children being diagnosed with nonspecific back pain, accounting for at least 50% of cases, paralleling adults in pathophysiology.[31-34] Children complaining of back pain require appropriate investigation. They may turn out to have spondylolysis with a variable degree of spondylolisthesis, Scheuermann's disease (kyphosis and osteochondritis of the vertebral endplates), an infectious disease, or a neoplastic process. Disk herniation in children is comparatively rare, but when it does occur, the presentation is similar to that in adults.[31]

CLINICAL FEATURES

Signs and Symptoms

A thorough history and physical examination are crucial in evaluating all patients with acute low back pain. The classic historical (Table 54-1) and physical findings with various entities associated with low back pain are reviewed in this section. Although most of these causative disorders are benign, four such disorders have been identified by the Agency for Healthcare Research and Quality (AHQR) as "cannot miss" or "red flag" diagnoses: spinal fracture, cauda equina syndrome, spinal infection, and malignancy.[5] A methodical and focused approach to the history and physical examination can help assess the patient's pretest probability for each of these disease entities and determine whether further tests should be ordered.

Table 54-1 Historical Clues to the Cause of Low Back Pain

QUESTIONS FOR PATIENT	POTENTIAL DIAGNOSIS
Does the back pain radiate down past the knees?	Radiculopathy and likely a herniated disk
Is the pain worse with walking and better with bending forward and sitting?	Spinal stenosis
Do you have morning back stiffness that improves with exercise?	Ankylosing spondylitis
Are you older than 50 years?	Osteoporotic fracture, spinal malignancy
Has there been any recent history of blunt trauma?	Fracture
Do you take long-term corticosteroids?	Fracture, spinal infection
Do you have a history of cancer?	Spinal metastatic malignancy
Does your pain persist at rest?	Spinal malignancy, spinal infection
Has there been persistent pain for longer than 6 weeks?	Spinal malignancy
Has there been unexplained weight loss?	Spinal malignancy
Is the pain worse at night?	Spinal malignancy, spinal infection
Are you immunocompromised (e.g., HIV infection, alcoholism, diabetes)?	Spinal infection
Have you had fevers or chills?	Spinal infection
Do you have pain, weakness, or numbness in both legs?	Cauda equina syndrome
Do you have bladder or bowel control problems?	Cauda equina syndrome

HIV, human immunodeficiency virus.

Uncomplicated Musculoskeletal Back Pain

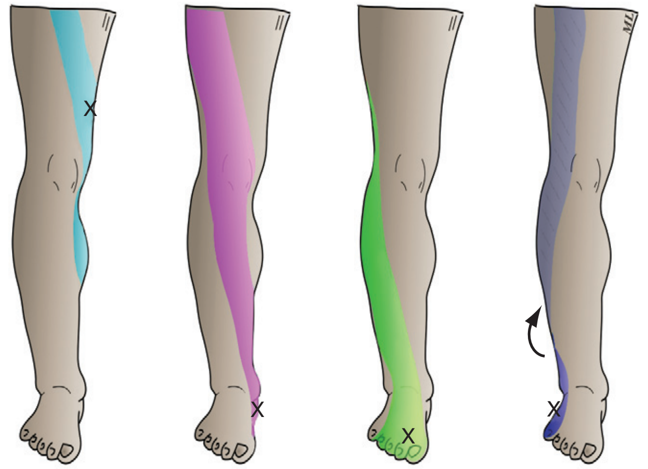
Most patients with back pain can be classified in the category of those with uncomplicated musculoskeletal back pain. These patients have no red flag findings in their history and on physical examination. Often, patients are unable to recall an inciting incident. The pain usually is characterized as an "ache" or "spasm" and is localized asymmetrically in the lumbar paraspinous muscle, with radiation to the buttock or posterior thigh proximal to the knee. Movement exacerbates the pain, and rest relieves it. No associated deficit in sensation, strength, or bowel or bladder sphincter tone is identified in the history or on the clinical examination. The sole physical findings may be regional lumbosacral tenderness and a limited range of motion of the lower back.

Radiculopathy

Approximately 1% of all patients with low back pain exhibit signs of lumbar radiculopathy (i.e., nerve root irritation).[35] The most common causative process is herniation of a lumbar disk; other causes include spinal stenosis, malignancy, and infection. The most common type of lumbar radiculopathy is an L5 or S1 radiculopathy causing sciatica symptoms. Patients with sciatica describe their pain as radiating from the low back to the legs, distal to the knee. Such pain is characterized as "shooting," "lancing," "sharp," or "burning." Associated symptoms include focal numbness or weakness in one of the lower extremities. Exacerbating triggers include sitting, bending, coughing, and straining; relieving factors include lying supine and still.

On physical examination the patient frequently exhibits tenderness to palpation in the sciatic notch. The *straight leg raise* (SLR) *test* is a fairly sensitive assessment tool to determine if the patient has sciatica. The SLR test is done with the patient supine and the legs extended. The symptomatic leg is passively raised while the knee is kept straight. The presence of back pain, which radiates past the knee when the leg is elevated 30 to 70 degrees, suggests an L5 or S1 radiculopathy. If the SLR test results in isolated low back pain without radiation symptoms to the legs, however, it is considered to be a *negative* finding. Through pooled analysis, the SLR test has a sensitivity of 91% but a low specificity of 26%, meaning that a negative result is fairly accurate in ruling out sciatica.[36] Corroborative tests for sciatica include the "bowstring sign" (reproduction of pain with deep palpation of the taut "bowstring" posterior tibial nerve in the midline popliteal fossa) and reproduction of pain with foot dorsiflexion when the leg is elevated just short of the pain threshold during the SLR test. As an alternative to the SLR test, with the patient in a seated position, the knee can be extended ("flip test"), which also should stretch the sciatic nerve. Reproduction of the pain often causes the patient

www.ketabpezeshki.com 66485457-66963820



Nerve root level	L3	L4	L5	S1
Pain location				
Stress test	R-SLR	R-SLR	SLR, C-SLR	SLR, C-SLR
Sensation (“X”)	Medial thigh	Medial foot	Between 1st and 2nd toe	Lateral foot
Strength	Hip flexion	Knee extension	Big toe/ankle dorsiflexion	Ankle plantar flexion
Reflex	—	Patellar	—	Achilles

Figure 54-2. Physical examination findings for L3-S1 radiculopathy. The X marks the ideal location to test for sensation for each nerve root. *C-SLR,* crossed straight leg raise; *R-SLR,* reverse straight leg raise; *SLR,* straight leg raise.

to lean backward reflexively from the pain, almost “flipping” back into a supine position.

A *crossed SLR test* is done by passively raising the patient’s asymptomatic leg while keeping the knee straight. The presence of pain radiating from the back to the opposite affected leg has a sensitivity of only 29% but a high specificity of 88% for sciatica, meaning that a positive result on crossed SLR testing is almost pathognomonic for sciatica, whereas a negative result is nondiagnostic.[36]

A *reverse SLR test* is performed to detect L3 or L4 radiculopathy. With the patient prone, each hip is passively extended. If there is irritation of the L3 or L4 nerve root, pain is elicited.

In addition to stressing lumbar nerve roots, a thorough examination of the lower extremities detects subtle abnormalities associated with radiculopathies. This examination includes mapping the distribution of pain and assessing individual nerve root function, specifically strength, sensation, and reflexes. For the sensory examination, the earliest deficit can be detected by examining the most distal aspect of the dermatome. Specifically, light touch and pinprick sensation should be tested on the medial foot (L4), in the area between the great and second toes (L5), and on the lateral foot (S1) (Fig. 54-2).

Herniated Disk

Patients with symptomatic herniated lumbar disks usually are 30 to 50 years of age and often have a long history of recurrent nonradicular low back pain, theoretically from irritation of the outer annular fibers of the disk. When the nucleus pulposus of the disk prolapses through the annulus fibrosus, local nerve root inflammation and radiculopathy result. Coughing, sitting, and any movement in general exacerbate the patient’s pain and radiculopathy symptoms. The severity of leg pain from radiculopathy often overshadows the back pain. Sciatica findings have a sensitivity of 95% for lumbar disk herniation, meaning that herniation is extremely unlikely in the absence of sciatica.

The physical examination should focus on lower extremity neurologic function and signs of radiculopathy. Weakness of ankle dorsiflexion, great toe extension, ankle plantar flexion, and knee extension is associated with respective specificities of 70%, 70%, 95%, and 99% for lumbar disk herniation.[20]

Spinal Stenosis

Patients with spinal stenosis are typically older (mean age of 55 years) and constitute only 3% of all patients with low back pain.[4,37] The classic history, identified in 60 to 75% of patients with spinal stenosis, is one of subacute or chronic pain and lower extremity radiculopathy that occurs with walking and is relieved with rest and, uniquely, bending forward at the waist.[38] Because these symptoms mimic peripheral vascular claudication symptoms, pain from spinal stenosis is termed *pseudoclaudication.* Typically, vascular claudication lasts 5 minutes after resting, whereas pseudoclaudication lasts 10 to 15 minutes. Patients with spinal stenosis obtain symptom relief with spine flexion and bending forward, because these maneuvers increase spinal canal diameter and reduce spinal cord tension. Similarly, sitting also helps to relieve the symptoms in these patients, in contrast with patients with herniated disks. A typical patient describes walking uphill without pain but experiencing pain on walking downhill, when the back is extended.

On physical examination, most patients are found to have a lumbar radiculopathy at one or multiple levels and increased back pain with extension.[38] Classically, patients with spinal stenosis walk with a slightly bent-forward position. To help differentiate spinal stenosis from vascular claudication, peripheral pedal pulses and ankle-brachial indices should be checked.

Degenerative Spondylolisthesis

Most cases of spondylolisthesis, forward displacement of one vertebral body over another, are caused by degenerative changes. This condition is most prevalent in adults older than age 50 and occurs most commonly at the L4-5 and L5-S1 junctions. Two thirds of older patients with radiographically documented degenerative spondylolisthesis are asymptomatic.[39] For patients with pain,

www.ketabpezeshki.com 66485457-66963820

bending, twisting, and lifting activities aggravate the symptoms. Radiculopathies, spinal stenosis symptoms, or both may coexist. On physical examination, clinical findings may include a loss of lumbar lordosis causing a change in posture, a step-off along the midline spine if the spondylolisthesis is severe, tight hamstrings resulting in decreased mobility of the hamstrings and subsequent "waddling" gait, or a radiculopathy.

Arthropathies

Inflammatory arthropathies, such as ankylosing spondylitis, rheumatoid arthritis, and psoriatic arthritis, all are associated with subacute and chronic low back pain. Patients with these conditions exhibit a decreased range of spinal flexibility. Commonly with ankylosing spondylitis, patients report morning back stiffness and pain relief with exercise. On physical examination, patients with an inflammatory arthropathy may have nonspecific manifestations, such as decreased spinal mobility, sacroiliac joint tenderness, and decreased chest expansion.

Red Flag Diagnosis: Fracture

In all patients who have experienced significant blunt trauma to the back or only minimal trauma in the setting of osteoporosis, fractures of the spinal column are considered. Chronic corticosteroid users deserve special attention, because they typically have developed some degree of osteoporosis. In a 20-year observation study of 2631 collagen vascular patients, vertebral fractures occurred in 23.9% of patients on high-dose corticosteroids as compared with only 2.6% of patients on no corticosteroids.[40] Thus providers should have a low threshold to assess this unique patient population for a fracture despite the absence of trauma.

Red Flag Diagnosis: Cauda Equina Syndrome

Cauda equina syndrome results from a sudden compression of multiple lumbar and sacral nerve roots. Although it is an extremely rare presentation of back pain, it constitutes a neurosurgical emergency. The usual cause is a massive central disk herniation, but other potential causative disorders include spinal epidural abscess, hematoma, trauma, and malignancy. Patients with cauda equina syndrome have back pain and multiple-level radiculopathies, often involving both legs. Difficulty with bladder or bowel function, specifically urinary retention or decreased rectal tone, respectively, also may be a feature. Diagnostic dilemmas arise because the presentation can be atypical with equivocal neurologic compromise and only mild to moderate pain.

The most consistent examination finding in cauda equina syndrome is urinary retention. Patients often complain of overflow incontinence owing to a neurogenic bladder. Given the high sensitivity of urinary retention of 90% and a negative predictive value of 99.99%, this disease process is extremely unlikely if the patient's postvoid residual urine volume is less than 100 to 200 mL. This can be measured by urethral catheterization or estimated by ultrasonography.[41] Saddle anesthesia—sensory deficit over the buttocks, upper posterior thighs, and perineal area—frequently is an associated finding, with a sensitivity of 75%. In 60 to 80% of cases, the rectal examination reveals decreased sphincter tone.[20]

Red Flag Diagnosis: Spinal Infection

Epidural abscess and spondylitis (osteomyelitis of the vertebral bone) are two types of dangerous spinal infections. Patients at higher risk include injection drug users, alcoholics, immunocompromised patients (e.g., patients with human immunodeficiency virus, diabetes mellitus, chronic renal failure, or long-term corticosteroid use), the elderly, patients who have sustained blunt trauma to the back, patients with an indwelling catheter or who have undergone recent dental instrumentation or instrumentation of the gastrointestinal or genitourinary tract or the spine, and patients with a recent bacterial infection.[42-45] With spinal epidural abscess, however, approximately 20% of patients have no comorbid illnesses or risk factors. The most common bacterial culprit is *S. aureus,* spreading hematogenously from a remote site or from direct extension of a local infection, such as spondylitis or disk space infection. Less common culprits are streptococcal strains and enteric gram-negative bacilli. Patient history reveals back pain even at rest and subjective fevers. On physical examination, there is often tenderness to percussion over the spinous process near the abscess location. Spinal epidural abscess remains a diagnostic challenge despite the "triad" of fever, focal back pain, and neurologic deficit, because approximately 50% of the patients have no neurologic deficits, and 50% may be afebrile on initial presentation.[46] With this subtle and often chronic presentation, many cases are misdiagnosed on initial presentation. Thus an awareness of this entity as a possible cause of low back pain is important for prompt diagnosis of this neurosurgical emergency, which carries a mortality rate as high as 15%.[46-48]

With spondylitis, infection often begins as a subtle hematogenous seeding of the disk space, causing diskitis. Subsequent contiguous spread of the disk space infection causes vertebral endplate erosion, leading to spondylitis. As with a spinal epidural abscess, the most common bacterial culprit is *S. aureus.* Less commonly, enteric gram-negative bacilli and *Mycobacterium tuberculosis* (in Pott's disease) are the infecting organisms. Injection drug users also are at risk for *Pseudomonas* spondylitis. The history typically reveals a more indolent course of back pain, with subjective fevers. The physical examination findings can range from nonspecific tenderness of the spine to radiculopathy and cauda equina syndrome. Similarly nondiagnostic, the presence of fever has a sensitivity of only 27 to 50% for spondylitis.[20]

Red Flag Diagnosis: Malignancy

Vertebral infiltration with a tumor can be caused by either a primary or, more commonly, a metastatic malignancy. Classically, affected patients generally are older than 50 years and often complain of subacute or chronic back pain that is worse at night. In a systematic review, a history of known cancer, a moderately elevated erythrocyte sedimentation rate (ESR) (≥50 mm/hr), a significantly elevated ESR (≥100 mm/hr), hematocrit less than 30%, and clinical judgment yielded positive likelihood ratios for a vertebral malignancy of 23.7, 18.0, 55.6, 18.2, and 12.1.[49,50] On examination, patients typically have mild to moderate spinal tenderness. Examination of the organs in which tumors are most likely to metastasize to bone, including breast, prostate, and lung, is indicated.

Referred Back Pain

Referred pain often is difficult to differentiate from pain originating from the lumbosacral structures. It is vital, however, to make the distinction. A sudden onset of severe, "tearing" back pain is classically an aortic dissection. Abdominal pain radiating to the back may be caused by a ruptured abdominal aortic aneurysm in an elderly patient with atherosclerotic disease. Alternatively, abdominal pain radiating to the back could be from pancreatitis in a chronic alcoholic. Unilateral paraspinal pain associated with fever and nausea in a young woman could indicate pyelonephritis. Other examples of conditions radiating to the back include biliary diseases, pneumonia, pulmonary embolism, renal colic, and retroperitoneal hemorrhage. In all such cases, a thorough examination of the abdomen, genitourinary system, and cardiovascular

www.ketabpezeshki.com 66485457-66963820

system is essential. Pinpointing the primary cause of the pain may radically alter the therapy for the patient.

Functional Back Pain

Distinguishing functional pain from "real" pain often is difficult, but several clues can be elicited from the history. A prolonged history of nonanatomic pain complaints, vague pain descriptions without localization, multiple lawsuits over similar problems, multiple prescriptions for narcotics from different providers, and lack of coordinated care for a problem that otherwise seems to dominate the patient's life all suggest that a search for a physical cause would be fruitless. In such cases, secondary gain for the patient's complaints often is likely.

On physical examination, maneuvers can be performed to try to detect functional back pain, if a psychological overlay is suspected. The first recommended maneuver is performing the SLR test from the sitting instead of the supine position. Seemingly focused on the knee examination, the physician extends the patient's knee; this physiologically reproduces the SLR by stretching the L5 and S1 nerve roots. A positive response includes reproduction of the patient's pain and extension of the back while seated to decrease traction on the sciatic nerve. A positive result on SLR testing in the supine position but a negative result in the seated position, and vice versa, suggests a nonphysiologic cause for the pain.

A second sign is apparent superficial tenderness. Some patients, to impress the physician with their degree of pain, respond dramatically to superficial palpation. This response is atypical for patients with genuine back pain. Nondermatomal sensory loss and widespread nondermatomal pain complaints also are unlikely to be caused by nonphysiologic processes.

Third, back pain should not be elicited by pushing down on the patient's scalp against the cervical spine. This maneuver axially loads only the cervical and not the lumbar spine.

Fourth, a patient who generally overreacts during the examination probably is not giving a true reflection of the actual discomfort. All of these signs are believed to correlate well with psychopathology but have poor prognostic value. They are suggestive of malingering and functional complaints but are neither sensitive nor specific enough to rule out organic pathology.[51,52]

Back Pain in the Elderly

In elderly persons with back pain, musculoskeletal processes and disk herniation are less likely causative disorders. Instead, spinal stenosis and degenerative spondylolisthesis should be considered. Also, the incidence of more worrisome diagnoses, such as an osteoporotic fracture, spinal infection, and malignancy, is much greater in this patient population. Consequently, in these cases the threshold for further investigation should be much lower.

Back Pain in Children

The likelihood of a congenital cause for back pain, such as leg-length discrepancy and spondylolisthesis, is greater for children than for adults. Spondylolisthesis is diagnosed most often in patients older than 10 years who are involved heavily in sports and complain of low back pain worsened with activity. In a retrospective study in an urban pediatric ED over a 1-year period, the most common causative disorders in patients with back pain complaints included direct trauma (25%), muscular strain (24%), sickle cell crisis (13%), idiopathic causes (13%), urinary tract infection (5%), and viral syndrome (4%).[31] A history suggesting infection or malignancy in children is similar to that in adults. Radicular symptoms are relatively rare in children. Functional processes are suggested when the pain is present only with certain undesired activities, such as housework or chores.

DIAGNOSTIC STRATEGIES

Laboratory Evaluation

In the absence of historical and physical findings suggesting red flag diagnoses for low back pain, laboratory evaluation is unnecessary. When a patient's back pain is suggestive of a spinal infection or malignancy, however, laboratory studies may help with risk stratification. Specifically, a complete blood cell count, ESR, and urinalysis should be performed. Additional laboratory studies should be tailored to the patient's history and physical examination findings. Liver function testing and determination of amylase or lipase level may be indicated to investigate abdominal complaints.

For a spinal infection, an ESR greater than 20 mm/hr has a sensitivity of 98%, and if the patient also has a spinal epidural abscess risk factor (e.g., diabetes, intravenous drug use history, chronic liver or kidney disease, recent spine procedure or indwelling spinal hardware, recent spine fracture, indwelling vascular catheter, immunocompromised state), then the sensitivity becomes 100% with a specificity of 67%.[53] The serum white blood cell (WBC) count, in contrast, may or may not be elevated.[54,55] In one study, 13 of 40 (33%) patients with a spinal epidural abscess had a falsely reassuring WBC count of less than 11,000/μL.[47] Thrombocytopenia (<100,000/μL), an extremely high ESR (≥110 mm/hr), and cervical spine epidural abscess are poor prognostic indicators and predictive of relapses and death.[56] When patients are diagnosed with a spinal infection, blood should be drawn for cultures because a single strain, most commonly *S. aureus,* can be isolated in 63 to 78% of the cases.[47,55,57] Performing a lumbar puncture to evaluate the cerebrospinal fluid is unnecessary and is relatively contraindicated because of the risk of seeding the fluid with bacteria.

With a bony malignancy the ESR also usually is elevated, whereas the WBC count may be equivocal. The hematocrit may be low secondary to anemia of chronic disease. Other additional helpful laboratory tests include measurement of alkaline phosphatase, prostate-specific antigen assay, and serum immunoelectrophoresis and urine testing for light chains (for multiple myeloma).

Radiology

Plain Radiography

The utility of "screening" lumbosacral plain radiographs for all patients with acute low back pain is extremely low; however, approximately one third of all patients with back pain–related disorders receive plain films, with increasing trends toward advanced imaging, including computed tomography (CT) and MRI.[58] Plain radiographs contribute little to patient management in the absence of concerning red flag findings and needlessly expose the patient to radiation.[59] Most patients with back pain do not need radiographs. In those cases in which radiographs have been obtained, normal findings are usual, but incidental findings, which may or may not be the true cause of the patient's pain, also are relatively common and may include spondylolisthesis, abnormal spinal curvature, disk space wedging, or degenerative changes.[10] Currently accepted indications for radiographs in patients with back pain are listed in Box 54-1.

Patients with radicular symptoms suggesting a herniated disk do not require radiographs. In addition to being undetectable on plain radiographs, disk herniations resolve with conservative management in most cases.

www.ketabpezeshki.com 66485457-66963820

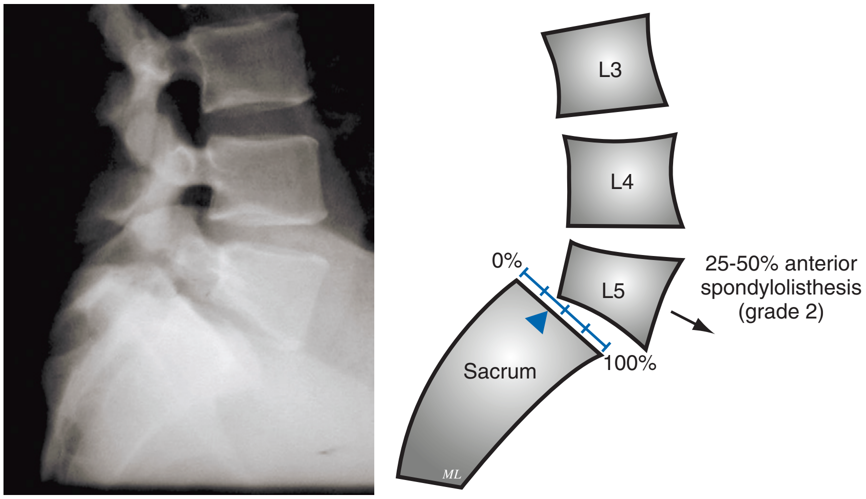


Figure 54-3. Lateral plain radiograph and schematic diagram of grade 2 anterior spondylolisthesis of L5 on S1. Grading is based on the percentage of slippage, with 0 to 25%, 25 to 50%, 50 to 75%, and greater than 75% corresponding to grades 1 to 4, respectively.

Box 54-1 Indications for Plain Lumbosacral Radiographs in Patients with Low Back Pain

- Age younger than 18 or older than 50 years
- Any history of malignancy or unexplained weight loss
- Any history of fever, immunocompromised state, or injection drug use
- Recent trauma, other than simple lifting
- Progressive neurologic deficits or other findings consistent with cauda equina syndrome
- Prolonged duration of symptoms beyond 4 to 6 weeks

If radiographs are obtained, anteroposterior and lateral views usually are sufficient in the ED, although many centers also prefer to obtain a cone-down lateral sacral view to improve visualization of the lumbosacral joint. Oblique views are not necessary except in children, in whom spondylolysis and spondylolisthesis may be more prevalent.[60]

On plain radiographs, spondylolisthesis, vertebral osteomyelitis, and vertebral metastatic disease have classic appearances. Spondylolisthesis (Fig. 54-3) is classified into grade 1 through grade 4 based on the severity of the anterior slippage of one vertebral body over another. Grade 1, which is often asymptomatic, involves less than 25% slippage. Grades 2, 3, and 4 involve 25 to 50%, 50 to 75%, and at least 75% slippage, respectively.

Spondylitis (Fig. 54-4) is characterized by erosion of contiguous vertebral endplates and a shortened disk space height, best seen on the lateral view. Because the anterior subchondral vertebral bone and disk space are highly vascular, it follows that spondylitis has a predilection for these areas because of the hematogenous spread of infection. With more advanced disease, vertebral bone erosion and collapse may occur.

Vertebral metastatic disease (Fig. 54-5) can manifest as either a blastic (hyperdense) or a lytic (hypodense) lesion and has a predilection for the vertebral body and pedicles. In contrast to osteomyelitis, in vertebral metastatic disease, the intervertebral disk space is spared.

If a red flag diagnosis is of concern, a plain radiograph may screen for a fracture but may not adequately rule out other pathologic processes, such as cauda equina syndrome, spinal infection, and malignancy. For cauda equina syndrome, patients more often have normal or nonspecific plain film findings because the most common cause is a central disk herniation. For spinal infection and vertebral malignancy, the sensitivity of a plain radiograph is only fair at 82% and 60%, respectively.[59] In these cases, the patient subsequently should undergo MRI if the there is a high clinical suspicion.

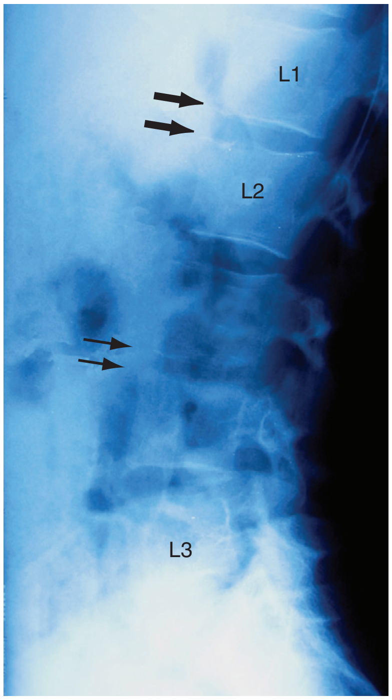

Figure 54-4. Lateral plain radiograph shows *Staphylococcus aureus* spondylitis of L3 and L4. There is narrowing of the L3-4 disk space and erosion of the vertebral endplates of L3 and L4 *(small arrows)*. Note the distinct vertebral endplate margins in unaffected areas *(large arrows)*.

Ultrasonography

In suspected cases of cauda equina syndrome, one should consider use of bedside ultrasonography to assess the postvoid residual volume of the bladder to help with risk stratification. An estimate of the postvoid residual can be obtained by measuring the bladder with ultrasound with the following formula: Volume (mL) = 0.52 × height (cm) × width (cm) × depth (cm).[41]

Computed Tomography and Magnetic Resonance Imaging

For assessment of fractures of the vertebral column, CT is superior to MRI. In the case of a fracture, CT helps to elucidate the integrity of the spinal canal and the risk for spinal cord impingement. For all other red flag diagnoses—cauda equina, spinal infection, and

www.ketabpezeshki.com 66485457-66963820

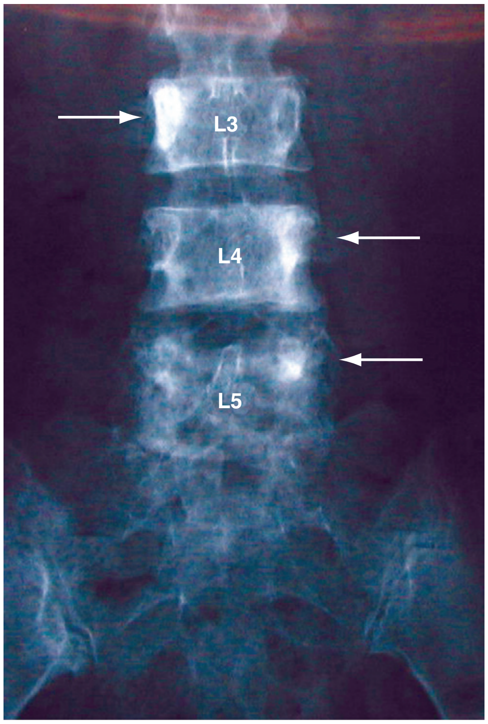

Figure 54-5. Anteroposterior plain radiograph shows blastic infiltration of metastatic breast cancer to the pedicles of L3 to L5 *(arrows)*.

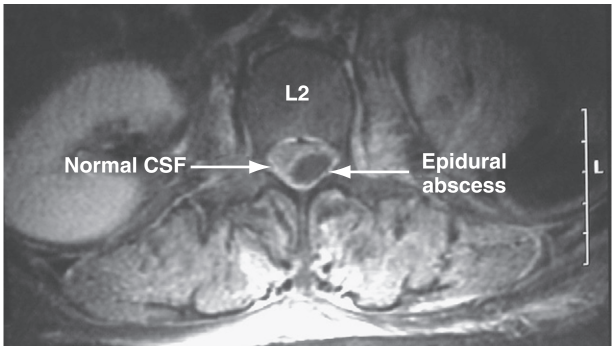

Figure 54-6. Axial T2-weighted magnetic resonance imaging of *Staphylococcus aureus* L2 epidural abscess impinging on the dorsolateral aspect of the spinal canal. *CSF,* cerebrospinal fluid. (Image contributed by Dr. Stephen Bretz.)

malignancy—MRI is the definitive investigative modality. Its superior tissue resolution, especially of the spinal cord and intervertebral disks, and its capability of generating more accurate sagittal reconstructions make MRI the ideal imaging modality. MRI is able to differentiate and detect subtle soft tissue pathology, such as a spinal epidural abscess (Fig. 54-6). No ionizing radiation exposure is incurred with MRI, whereas one CT scan of the entire spine exposes the patient to the equivalent of approximately 18.8 years of natural background radiation—cervical spine, 2 years; thoracic spine, 8.8 years; and lumbar spine, 8 years.[61] For patients who have contraindications to MRI (e.g., pacemaker, metallic implants), a CT myelogram can be performed to assess for spinal cord impingement, cauda equina syndrome, and spinal epidural abscess. A spine CT scan can be performed to assess for vertebral bone infiltration by malignancies.

Although disk herniation is easily visualized on MRI, patients with findings consistent with an uncomplicated disk herniation (i.e., without objective findings of motor or sensory deficit on examination) should not routinely undergo MRI imaging because of the self-limited nature of the disease in most cases. Overimaging in patients with lumbar radiculopathy is costly and may lead to an overdiagnosis of disk herniations because incidental MRI-documented herniations have been shown to be present in 28 to 33% of asymptomatic patients. The result may be unnecessary surgical intervention.[10,22,62]

Special Investigations

Most cases of back pain in the ED do not require any diagnostic tests. Additional workup is warranted only when red flag conditions are suspected. Radionuclide scans have been used for locating suspected malignancy, infectious foci, and occult fractures as in spondylolysis. Nuclear medicine scans are regarded as sensitive but nonspecific.

DIFFERENTIAL CONSIDERATIONS

Nonspecific low back pain is in many ways a diagnosis of exclusion. In a typical patient, within the 18- to 50-year age range with acute low back pain and with no radiculopathy, previous malignancy, weight loss, risk factors for spinal infection, or fever, the diagnosis is almost certainly uncomplicated musculoskeletal back pain. When the patient falls outside of the aforementioned parameters, a wide variety of diagnostic possibilities should be entertained.

Almost anything can cause low back pain. Box 54-2 presents an extensive list of diagnostic considerations, but it is useful to look at the most common and most serious causes of low back pain other than musculoskeletal lumbosacral pain. One of the most life-threatening causes of referred back pain is a leaking or ruptured abdominal aortic aneurysm. The reader is referred to appropriate chapters for further discussion of specific problems.

MANAGEMENT

Because most patients with acute low back pain without objective sensory or motor loss on examination experience symptomatic resolution within 4 to 6 weeks, only conservative management is needed. In general, MRI and surgery are reserved for the few patients who have worrisome systemic signs and patients with refractory, debilitating back pain. Over the past few decades, the accepted practice has shifted 180 degrees, from an overaggressive recommendation for invasive surgical intervention to the minimalistic recommendation of symptomatic pain control and early return to activity. In one large prospective study, the randomized intention-to-treat analysis found no significant difference in the outcomes of surgical versus nonsurgical treatment of degenerative spondylolisthesis.[63] Thus the recommended role of the emergency physician in back pain management is to arrive at a correct diagnosis, rule out significant pathology, avoid excessive investigation, provide analgesia, and educate the patient.[64] The management for various etiologic categories of disorders that may cause low back pain is summarized in Figure 54-7. For management of fractures and referred pain, the reader is referred to the appropriate chapters.

Uncomplicated Musculoskeletal Back Pain

Besides a thorough history and physical examination, no further investigations are required for uncomplicated low back pain. Only pain control and patient education are indicated. Aside from an initial parenteral opioid or nonsteroidal anti-inflammatory drug (NSAID), most patients can be managed with oral nonsteroidal medications. Ibuprofen is an ideal choice because it is inexpensive, but various NSAIDs can alternatively be used because they

have been shown to have similar efficacy. It is unclear whether NSAIDs are superior to acetaminophen, but it is known that acetaminophen has fewer side effects than NSAIDs.[65,66] Selective cyclooxygenase-2 (COX-2) inhibitors are equally effective compared with NSAIDs, with fewer side effects than traditional NSAIDs; however, COX-2 inhibitors now are rarely used because of recent studies showing an increased cardiovascular risk in certain populations.[66] Short-term opioids also occasionally are needed for breakthrough pain in the acute setting. Various other medications have been advocated, including benzodiazepines and other muscle relaxants. Based on the current conflicting literature, these medications probably do not provide a significant added benefit, but they do increase the incidence of side effects such as drowsiness, falls, accidents, and drug dependence.[67] Corticosteroids are not significantly beneficial in the treatment of uncomplicated low back pain.[68,69]

In terms of patient education, one of the outdated practices of back pain management was that physicians convinced patients that they were sick. This was done by excessively investigating and overtreating patients, restricting patients to strict bed rest, and taking them off work. It now has been shown convincingly and repeatedly that all of those interventions are unnecessary. Instead, patients should be educated about why they are not undergoing radiographic studies of their lumbosacral spine or laboratory tests and should be reassured of the likely benign course of the pain. Most patients can be convinced by education and an explanation of radiation dosage. A typical lumbosacral spine series involves as much gonadal irradiation as that incurred with a daily chest radiograph for 5 to 6 years.[70] Patients also are discouraged from the outdated recommendation of strict bed rest. Compared with patients who are prescribed strict bed rest, patients with acute back pain who remain active experience earlier resolution of pain and return to work sooner.[4] Patients should be made aware, however, that the back pain has a 66 to 84% likelihood of recurring within 12 months.[11]

Other supplemental treatment modalities have been shown to be of debatable efficacy in the management of acute and chronic low back pain. These include acupuncture, physiotherapy, chiropractic manipulation, massage, ultrasound, traction, and transcutaneous nerve stimulation.[10,71-74]

Lumbar Disk Herniation

Like patients with uncomplicated low back pain, patients with disk herniations and radiculopathy do not benefit from strict bed rest.[5,64] In the acute setting, these patients should receive analgesics. Further investigation with laboratory tests and radiographs is not necessary. Most of these patients experience symptomatic resolution within 6 weeks with conservative, nonsurgical management.[75,76]

Corticosteroid injections into the epidural space have been advocated for sciatica in the belief that this treatment helps to relieve some of the inflammation associated with disk herniation. Although some reduction of symptoms may be obtained initially, no long-term benefit or reduction in the need for later surgery has been documented.[77-79] The use of systemic steroids in back pain

www.ketabpezeshki.com 66485457-66963820

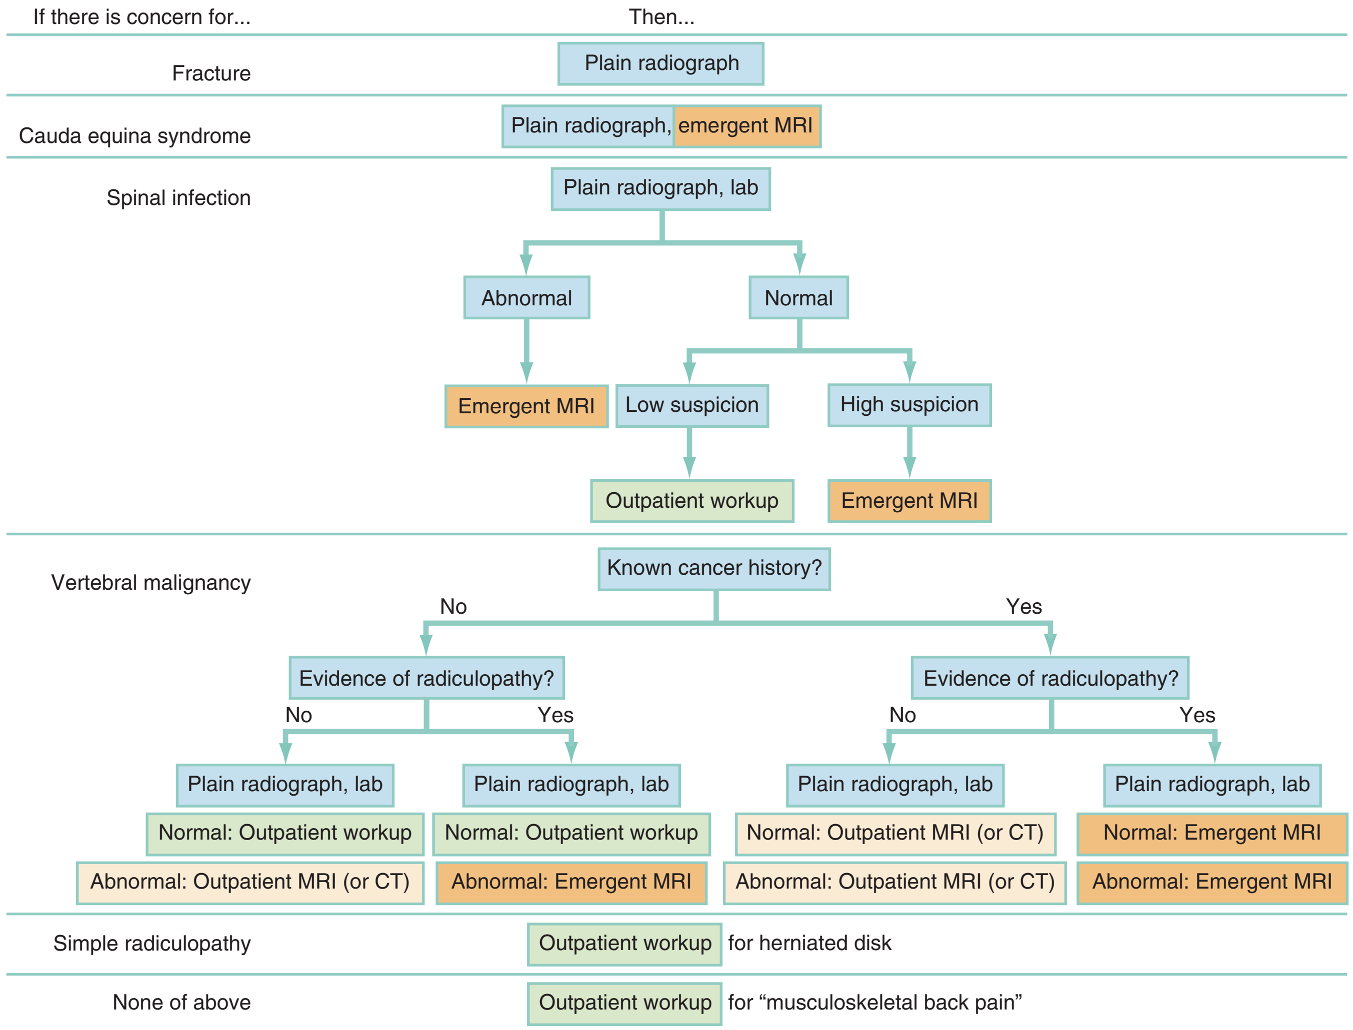

Figure 54-7. Algorithm for management of low back pain. The patient’s history may be concerning for more than one red flag diagnosis. *CT,* computed tomography; *MRI,* magnetic resonance imaging.

and disk herniation remains controversial. Although there is no proven benefit, the anti-inflammatory effects make empirical sense in the context of radiculopathy. A large retrospective review showed no definite benefit of systemic steroids in either presentation, but the definitive trial is yet to be done.[67] When the pain from disk herniation persists for longer than 4 to 6 weeks, outpatient MRI is indicated. With a documented herniation, these patients may benefit from surgical diskectomy, although this remains controversial compared with conservative management.[80] Other potential indications for surgery include intractable pain and worsening motor or sensory deficit. Although surgical patients tend to have earlier relief of pain compared with nonsurgical patients, the 4- and 10-year results are the same. Microsurgery techniques and laser therapy have not been shown to confer any advantage over conventional techniques.[81]

Spinal Stenosis

Patients with spinal stenosis should be managed conservatively with pain medications. In the absence of alarming red flag findings, these patients do not require laboratory or radiographic studies in the ED. These patients may be candidates for surgery if they show any of the following conditions: progressive neurologic deficit, progressive reduction in ability to walk secondary to pseudoclaudication, evidence of cauda equina syndrome, or intractable pain. Elective surgical decompression is more controversial. A 10-year longitudinal study showed that no findings predicted which patients would benefit more from surgery than from conservative management.[82] The benefits of surgery also are weighed against the risks of surgery itself, because these patients usually are elderly.

Degenerative Spondylolisthesis

Patients with symptomatic degenerative spondylolisthesis are managed conservatively with analgesia and lifestyle changes, which include the avoidance of repetitive bending, heavy lifting, and twisting at the waist. For patients with refractory or severe back pain, outpatient MRI and neurosurgical referral for possible operative decompression are recommended.

Red Flag Diagnosis: Fracture

See Chapter 43, Spinal Injuries.

Red Flag Diagnosis: Cauda Equina Syndrome

Cauda equina syndrome is a neurosurgical emergency that requires urgent operative decompression to help preserve distal neurologic function. All patients with concerning findings, such as saddle anesthesia or a large postvoid residual volume, require emergent

www.ketabpezeshki.com 66485457-66963820

MRI. On average, outcome is improved if decompression takes place within 48 hours of symptom onset.[83] Although the standard of care is for emergent decompression, preliminary evidence suggests that delayed operative decompression for selected patients in a more controlled setting may be performed without any adverse effects, particularly in patients who have overflow urinary incontinence.[84]

Red Flag Diagnosis: Spinal Infection

If findings on the history or physical examination are worrisome for a spinal infection, further investigation is of paramount importance. In low-risk patients, normal results on serum WBC count, ESR, and lumbosacral plain radiograph can safely rule out infection. In patients with a moderate to high pretest probability for a spinal infection, the next step is to perform emergent MRI.

Pyogenic spinal infections should be treated with neurosurgical drainage and decompression, in addition to broad-spectrum intravenous antibiotics that cover at least for *S. aureus* and gram-negative bacilli until blood culture results return. Vancomycin should be included in the antibiotic regimen, given the increased prevalence of methicillin-resistant *S. aureus.* In a case series from 2003 to 2008, *S. aureus* accounted for 67% of the 45 cases of adult spinal epidural abscesses. Of this group, 41% were oxacillin/methicillin-resistant strains.[85] For injection drug users, antibiotic coverage for *Pseudomonas* is necessary. The recent literature suggests that a nonsurgical management approach may be acceptable for a select group of patients at lower risk, such as those who are hemodynamically stable and neurologically intact.[85]

Red Flag Diagnosis: Malignancy

Patients with a known malignancy who report back pain and have an associated neurologic deficit require emergent MRI to rule out spinal cord compression. However, patients who have no myelopathic findings pose a greater diagnostic challenge. A suggested algorithmic guideline in the diagnostic evaluation of back pain that is worrisome for malignancy involves subdividing patients into two categories: patients with and patients without a history of previous cancer. Development of spinal metastasis has been reported in 20 to 85% of patients with cancer.[86,87] These patients are subdivided further into those with and those without evidence of a radiculopathy.

Most patients fall into the classification of *back pain without a history of cancer and without a radiculopathy.* They have a history that is only suggestive of a malignancy, such as unexplained weight loss or back pain that is worse at night. These patients require further risk stratification with plain radiographs (or a spine CT scan for patients with a high pretest probability for malignancy) and laboratory tests, including a complete blood cell count and ESR. With normal results, these patients can be referred to their primary care physician for further workup. The physician should not feel completely reassured that malignancy has been ruled out with plain films, however, because they have a false-negative rate of 10 to 17% for vertebral bone metastasis. This false-negative rate is likely a result of the fact that a cancer needs to erode at least 50% of the bone before becoming radiographically apparent on plain films.[88] With abnormal results, such as a bone lesion or an extremely elevated ESR level (above 100 mm/hr), an urgent CT scan or MRI should be performed on an outpatient basis within the following 3 to 7 days, assuming that there are no neurologic deficits.

For patients *without a history of cancer but with signs of radiculopathy,* the workup also includes a plain radiograph, complete blood cell count, and ESR. If the test results are normal, the patient should be referred to his or her primary care physician for further evaluation for malignancy and other potential causes of radiculopathy, including spinal stenosis and disk herniation. If the workup shows a bone lesion on plain radiographs or an extremely elevated ESR level (greater than 100 mm/hr), the patient should undergo emergent MRI because (1) the presence of radiculopathy may be an early harbinger of impending spinal cord compression from a mass effect and (2) it often is difficult on plain radiography to distinguish between a neoplasm from early spondylitis (especially tuberculous osteomyelitis) and an osteoporotic fracture causing a vertebral collapse.[89] If MRI is unavailable, multidetector CT imaging can be performed initially to screen for the presence of malignant bone infiltration, although definitive spinal cord and nerve root imaging will require MRI. The presence of a vertebral mass lesion on CT images suggests nerve root compression as a cause of the pain.

For patients *with a history of previous cancer and low back pain,* advanced imaging is indicated, either emergently or urgently within 3 to 7 days. In the absence of clinical manifestations of radiculopathy, these patients should undergo outpatient MRI (or CT, if MRI is not available or is contraindicated) regardless of plain radiography findings and laboratory results. Plain radiography is too insensitive to rule out a vertebral neoplastic process definitively. If a radiculopathy is present, however, these patients require emergent MRI regardless of plain radiography findings because of the concern for spinal cord compression. In a study of patients with a known diagnosis of cancer who had back pain and radiculopathy, the risk of epidural spinal cord compression was 25% despite normal radiographic findings, and 88% with radiographic evidence of vertebral metastasis.[90]

In all patients undergoing emergent MRI to evaluate for vertebral malignancy and spinal cord compression or cauda equina syndrome, dexamethasone should be administered as soon as these conditions are suspected to reduce the potential mass effect. In the setting of a diagnosed neoplasm causing spinal cord compression or cauda equina syndrome, emergent radiation therapy and potentially spinal surgery should be arranged.

Pediatric Back Pain

Management of back pain in children is similar to management in adults and depends on the underlying causative disorder. Spondylolisthesis is managed by observation, with only 4 to 5% of cases worsening. Progression usually stops as skeletal maturity is achieved in the late teens. Current recommendations are for limited contact sports in children with less than 30 to 50% slippage who are asymptomatic with conservative therapy (activity, rest, physiotherapy, and brace) and avoidance of loading the spine in a hyperextended position. Surgical stabilization for children may be indicated with slippage greater than 30 to 50%. Treatment becomes more aggressive if the child is symptomatic or if radiologic evidence of further displacement is present.[91]

Chronic Back Pain

Patients with chronic back pain often are regarded as the most challenging of all patients with back pain. The cause of chronic back pain is complex and multifactorial and usually requires a multidisciplinary approach for the greatest chance of success. Psychosocial factors, including depression, drug dependence, and financial gain, undoubtedly play a significant role in the behavior of many of these patients, making proper assessment and treatment extremely challenging in the ED.

After appropriate evaluation has ruled out a red flag cause for the back pain, ED management involves analgesia and referral for follow-up care. The main decision usually centers on the use of narcotics, which should be individualized in accordance with the physician's assessment of the clinical scenario. Patients exhibiting

www.ketabpezeshki.com 66485457-66963820

drug-seeking behavior classically are from out of town, have a primary care physician who cannot be contacted, or are reportedly allergic to all nonopioid medications.

DISPOSITION

Almost all patients with uncomplicated back pain can be discharged from the ED with follow-up with their primary care physician. In rare circumstances, severe pain or inadequate support for convalescence at home may preclude discharge. For patients who have a red flag diagnosis of spinal cord compression or cauda equina syndrome or spinal epidural abscess, immediate neurosurgical consultation is required for emergent surgical decompression. Although less emergently, consultation with a neurosurgeon or orthopedic spine specialist is necessary for patients with spine fractures, spondylitis, or a new vertebral malignancy in the absence of spinal cord or cauda equina involvement. Most patients with a spine fracture require hospitalization for pain control, fracture stabilization, and/or assessment of concurrent injuries. Some patients with stable fractures (e.g., small wedge fracture of the vertebral body) and tolerable pain can be managed on an outpatient basis. For patients with spondylitis, hospitalization will be necessary for administration of intravenous antibiotics. For patients with a vertebral malignancy, the decision to hospitalize the patient for pain control, administration of high-dose corticosteroids, and radiation therapy should be made in conjunction with a neurosurgeon, an oncologist, and a radiation therapist.

One of the most important aspects of management of low back pain is the discharge instructions for the patient. Not only are clear and simple directions useful to the patient, but they also constitute a medicolegal necessity for the physician. Physicians are advised to avoid use of purely medical terms. The discharge instruction should include the following:

1. *Diagnosis*: Distinguish between uncomplicated (musculoskeletal) back pain and diskogenic radiculopathy.
2. *Activity*: Recommend maintaining active mobility as limited only by pain, avoiding heavy lifting until symptoms resolve, and getting back to full activity as soon as possible. Also teach patients how to properly lift heavy objects in the future. This includes positioning the object closer to the body, standing with feet shoulder-width apart, keeping the back straight, tightening the abdominal muscles, and lifting with the knees.
3. *Reassurance*: Educate patients about the likely benign nature of the causative condition responsible for the pain.
4. *Warnings:* Instruct patients to return to the ED immediately if they experience any of the following: fever; loss of bladder or bowel control; numbness or tingling around the anus, vagina, or penis; or new pain or weakness down one or both legs.

In patients with pain secondary to spondylolisthesis, activity restrictions should be made in conjunction with an orthopedic surgeon. ED disposition for a patient with chronic back pain is relatively simple: pain management with nonopioids, when possible, and referral to a primary care physician for follow-up care. The prognosis is guarded because patients who are off work for 6 months usually are still off work after 2 years.[29] Pediatric patients with back pain require the same discharge instructions as adults.

UPPER BACK PAIN

PERSPECTIVE

Background

Thoracic pain is far less common than low back pain. Thoracic pain usually has a musculoskeletal origin, but other, more emergent causes are considered first, including thoracic aortic dissection, pulmonary embolism, and esophageal disease. Compared with lumbar disk herniation, which is fairly common, thoracic disk disease is extremely rare, difficult to diagnose, and difficult to treat.

Epidemiology

The actual incidence of thoracic pain is unknown. The incidence of symptomatic thoracic disk disease is low, with estimates at 1 in 1 million.[92] The average age is in the 40s with equal gender distribution. Surgery for thoracic disks accounts for less than 4% of all disk operations.[93] Metastases are more common in the thoracic spine than in the lumbar spine, with 60 to 70% of spinal metastases localizing there.[10,94]

PRINCIPLES OF DISEASE

Anatomy and Physiology

The thoracic vertebral column can be regarded as an extension of the cervical column with the addition of ribs. There are 12 thoracic vertebrae, connected by the anterior and posterior longitudinal ligaments and the ligamentum flavum, similar to the lumbar vertebrae. Also similarly, intervertebral disks provide elasticity and stability to the thoracic column. The spinal canal diameter remains unchanged through the thoracic and lumbar levels, but at the thoracic level, the space around the spinal cord is smaller than at the lumbar level. Because lumbar nerve fibers have not yet branched off from the spinal cord, the thoracic cord is thicker than the lumbar cord. Significant neurologic abnormalities may result from minimal spinal canal impingement at the thoracic level.

Pathophysiology

Common thoracic soft tissue pain is likely to be a combination of sprain and muscle inflammation. As in the lower back, innervation of the paravertebral area is provided by the sinuvertebral nerve, and any anatomic disruption of surrounding structures results in nonspecific pain. Thoracic disk herniations, which most commonly occur in the midthoracic to lower thoracic spine, cause pain and neurologic symptoms in much the same way as for lumbar disks. It is not clear why the clinical presentation is so varied, although a possible cause is a higher number of centrally herniated disks, resulting in much more frequent myelopathic symptoms.[93]

CLINICAL FEATURES

Symptoms and Signs

History

Nondiskogenic thoracic back pain usually manifests as paraspinal discomfort. A history of trauma or recent unusual activity may or may not precede the onset of pain. Complaints with thoracic disk herniations are variable but usually are associated with long-standing pain, neurologic symptoms, or both. Pain may be localized to one part of the thoracic vertebrae, it may radiate down to the sacrum, or it may have a radicular component along the ribs. Central disk herniation can manifest as diffuse abdominal and back pain or a burning sensation in the lower extremities. Associated findings may include mild weakness, spasticity, gait disturbance, bowel or bladder dysfunction, and paraplegia. These usually progress until the condition is diagnosed. Because of the variable and often subtle signs and symptoms, thoracic disk disease typically is not diagnosed until 20 months after the first clinical presentation. Pain from other causes should be sought in the initial assessment. A history of trauma, fever, previous malignancy, cardiovascular disease, or gastrointestinal problems may indicate more worrisome conditions or those originating from outside the thoracic spine and may warrant further investigation.

www.ketabpezeshki.com 66485457-66963820

Physical Examination

In patients with benign musculoskeletal pain, the physical examination fails to disclose evidence of a pathologic process. These patients may experience mild to moderate paraspinal tenderness to palpation, pain with motion, and even discomfort from chest wall expansion with respirations, but objective findings are minimal.

Physical findings in patients with thoracic disk herniation will vary with the location and degree of herniation. Objective findings may range from a normal-looking spine to loss of posterior column function (position, touch, vibration) or unilateral or bilateral weakness. Gait and sensory abnormalities are common. Hypotonic abdominal reflexes, elicited by scraping the skin tangential to the umbilicus in a particular quadrant, causing contraction of abdominal muscles in that quadrant, may be present with distal hyperreflexia. Babinski's response may be present. Myelopathy may result in urinary retention. Muscle wasting may be present with chronic symptoms. The possibility of other pathologic conditions should be kept in mind during the physical examination, with appropriate assessment tailored to the presentation and level of clinical suspicion.

DIAGNOSTIC STRATEGIES

Laboratory Evaluation

In the face of unremarkable history and physical examination findings, the likelihood that laboratory evaluation will yield useful results is extremely small. In appropriate clinical circumstances, assessment for malignancy, infection, and inflammation should be undertaken.

Radiology

The usefulness of radiologic assessment is dubious in a patient with acute atraumatic thoracic back pain in whom preexisting illness or neurologic abnormalities are absent. As a general guide, however, the following factors should prompt basic radiologic studies and appropriate further investigations: clinical suspicion for presence of other conditions; unexplainable symptoms; extremes of age; concern for trauma, tumor, infection, gastrointestinal pathology, or vascular pathology; and prolonged symptoms. Like patients with lower back pain, patients with a history of cancer and upper back pain should undergo plain radiography (or CT or MRI for high-suspicion cases) to assess for vertebral metastatic disease, especially because metastases have a predilection for the thoracic spine.

MRI has become the modality of choice for evaluating a herniated thoracic disk. The incidence of asymptomatic disk herniations seen on MRI is 37%. Most herniated thoracic disks, whether symptomatic or not, have been reported to recede spontaneously.[92]

DIFFERENTIAL CONSIDERATIONS

Although muscular back pain is extremely common, Box 54-3 summarizes the important considerations in the expansive differential diagnosis for thoracic back pain.

Box 54-3 Differential Diagnosis for Thoracic Back Pain

- Uncomplicated musculoskeletal back pain
- Spinal cord and nerve root pathology (e.g., disk herniation, tumor, hematoma)
- Vertebral column disease (e.g., primary or metastatic malignancy, osteomyelitis)
- Disk infection
- Primary neurologic disease
- Degenerative and autoimmune arthropathies
- Herpes zoster
- Vascular disease (e.g., thoracic aortic dissection, acute coronary syndrome, pulmonary embolism)
- Thoracic cavity pathology (e.g., pleuritis, pericarditis, pneumonia, esophageal pathology)
- Intraperitoneal and retroperitoneal abdominal pathology (e.g., peptic ulcer disease, pancreatitis, hepatobiliary disease)

MANAGEMENT

Commonly, thoracic musculoskeletal pain is managed with analgesia. No studies have shown the need for any difference in management from that for musculoskeletal back pain.

Thoracic disk disease is difficult to diagnose and manage. Symptomatic pain management and outpatient follow-up care are recommended. In view of the limited space in the spinal canal at the thoracic level compared with the lumbar level, spinal cord compression from a herniated disk is more likely at the thoracic level. Any disk herniation that precipitates an acute neurologic deficit warrants MRI and early neurosurgical evaluation.

DISPOSITION

Patients with benign back pain in any part of the thoracic vertebral column can be discharged with referral for follow-up care by the primary care physician. Patients with a suspected thoracic disk herniation require close outpatient follow-up. Most cases of subjective discomfort resulting from thoracic disk disease without objective neurologic findings resolve spontaneously, with one study showing a 77% improvement rate.[92] Although clear guidelines are lacking for when emergent neurosurgical consultation is required for thoracic disk herniation, patients with significant pain or neurologic compromise should be assessed rapidly.

KEY CONCEPTS

- The key to differentiating between benign and serious pathology in low back pain is a focused and thorough history and physical examination.
- The absence of sciatica findings practically rules out a lumbar disk herniation.
- Screening laboratory tests and plain radiographs are not indicated for patients with uncomplicated low back pain or a simple disk herniation.
- The best treatment for uncomplicated back pain and disk herniation is analgesia and resumption of normal activities—not bed rest.
- Age younger than 18 or older than 50 years, fever, injection drug use, immunocompromised status, symptoms lasting more than 4 to 6 weeks, night pain, and previous malignancy all are red flag warnings of potentially serious causes of back pain and should be heeded and evaluated accordingly.
- Although thoracic disk herniation can result in significant upper back pain, other, more dangerous causative disorders, such as aortic dissection, pulmonary embolism, and acute coronary syndrome, are considered first.
- The associated findings on the neurologic examination with thoracic disk herniations can be extremely variable, ranging from nonspecific paresthesias to significant upper motor neuron weakness.
- The incidence of vertebral metastatic malignancy is higher in the thoracic spine than in the lumbar spine.

CHAPTER 55

Pelvic Trauma

Stephen B. Choi and A. Adam Cwinn

PERSPECTIVE

Background

Patients with traumatic pelvic ring injury may represent an immense challenge for the emergency physician. First, patients with pelvic ring fractures are at risk for exsanguinating pelvic hemorrhage. Furthermore, the profound magnitude of force required to disrupt the pelvic ring frequently causes severe injuries to other organ systems. The resuscitation from hemorrhagic shock, rapid identification of other major injuries and sites of blood loss, and the coordination of definitive angiographic and surgical treatments are paramount to achieving good clinical outcomes.

Epidemiology

Based on data from trauma registries, the majority of high-energy pelvic ring injuries are caused by motor vehicle collisions (MVCs), motorcycle crashes, and pedestrians being struck by motor vehicles, together accounting for 80 to 84% of pelvic fractures; and falls from height, which account for 5 to 12%[1-5] of pelvic fractures. The mortality rates reported in the literature associated with pelvic fracture range from 9 to 22%[1-5]; in studies of large cohorts of trauma patients, the presence of pelvic fracture has been consistently shown to be an independent risk factor for death compared with trauma patients without pelvic fracture.[6-8] Patients with pelvic fractures and with shock on arrival to the hospital have mortality rates of 33 to 57%.[3,4] Increased age, shock on arrival at the hospital, high injury severity and revised trauma scores (which generally reflect the presence of multisystem injuries), and the need for transfusion have all been shown to increase the risk of death.[3-5,9,10] The mortality rate among pedestrians struck by motor vehicles who sustain pelvic injury has been shown to be 23%.[11]

Despite advances in motor vehicle safety design, MVCs continue to be a major cause of pelvic fracture. Rates of pelvic fracture secondary to MVC range from 10 to 28%.[9,12,13] Lateral impact remains the most prevalent mechanism for pelvic trauma in collisions, for which the widespread advent of front airbags has little effect. Some have speculated that the increased popularity of sport-utility vehicles in past decades is contributing to the severity of side-impact injuries, specifically as a result of the higher bumper in these vehicles striking the side of lower cars.[9,12,14]

PRINCIPLES OF DISEASE

Anatomy

Detailed descriptions of pelvic anatomy may be found in standard anatomy texts. This section focuses on the relevant anatomy essential to understanding pelvic injuries.

Bony and Ligamentous Anatomy

The pelvic ring is made up of right and left innominate bones and the sacrum. The innominate bones consist of the pubis, ischium, and ilium (Fig. 55-1). The bony pelvis provides protection for its visceral contents, serves as attachment points for muscles, and transmits weight from the trunk to the lower limbs. The main weight-bearing forces are transmitted through the posterior wall of the pelvis, called the *posterior arch*, which is composed of thick bone and ligaments. The rich network of major arteries, veins, and nerves that course in front of the posterior arch may be injured concomitantly with forces causing bony injuries of this arch.

Knowledge of the ligamentous attachments of the pelvic ring is crucial to understanding how stability is maintained or disrupted in pelvic injury. The stability of the pelvis is maintained by ligaments, as well as the muscles and fascia that make up the pelvic floor. Anteriorly, the symphysis pubis provides the major mechanical stability. Posteriorly, a complex of strong ligaments—the sacrospinous, sacrotuberous, iliolumbar, and anterior and posterior sacroiliac (SI) ligaments—maintains the integrity of the posterior arch (Fig. 55-2). It is important to appreciate that mechanically unstable pelvic fractures are unstable primarily because of the disruption of these posterior ligaments.

Vascular Anatomy

Most of the blood supply to the pelvis comes from the left and right internal iliac arteries. The internal iliac arteries course at the level of the SI joints. The various arteries that derive from the internal iliac arteries initially run in close proximity to the posterior pelvic arch and eventually anastomose extensively with one another, forming a rich collateral network (Fig. 55-3). The superior gluteal artery is the largest branch and is commonly injured in fractures of the posterior pelvic arch. The obturator and internal pudendal branches are often injured in fractures involving the pubic rami.

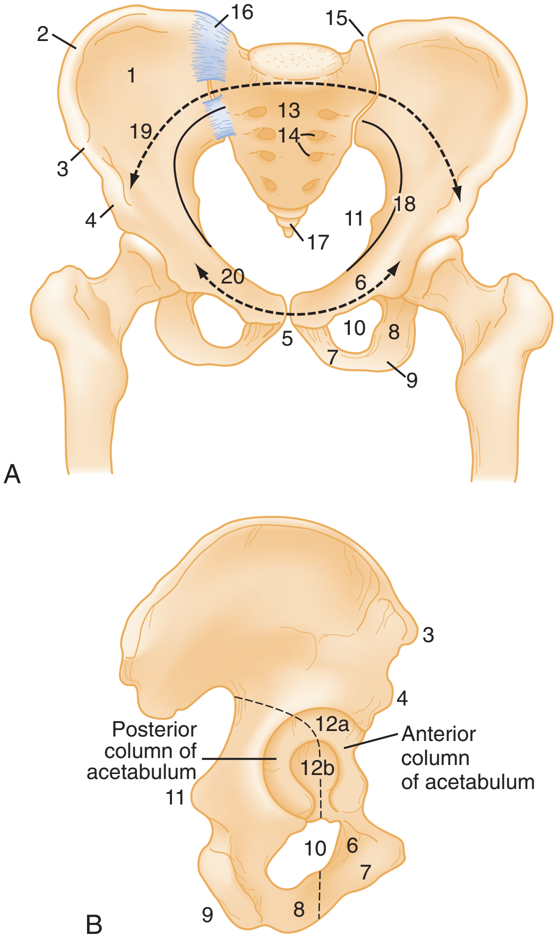

Figure 55-1. Bony pelvic anatomy. **A,** Anterior view of pelvis. **B,** Lateral view of right innominate bone. *(1)* Iliac fossa, *(2)* iliac crest, *(3)* anterior superior iliac spine, *(4)* anterior inferior iliac spine, *(5)* symphysis pubis, *(6)* superior ramus of pubis, *(7)* inferior ramus of pubis, *(8)* ramus of ischium, *(9)* ischial tuberosity, *(10)* obturator foramen, *(11)* ischial spine, *(12)* acetabulum (*[12a]* articular surface, *[12b]* fossa), *(13)* sacrum, *(14)* anterior sacral foramina, *(15)* sacroiliac joint, *(16)* anterior sacroiliac ligament, *(17)* coccyx, *(18)* arcuate line, *(19)* posterior or femorosacral arch, through which main weight-bearing forces are transmitted, *(20)* anterior arch.

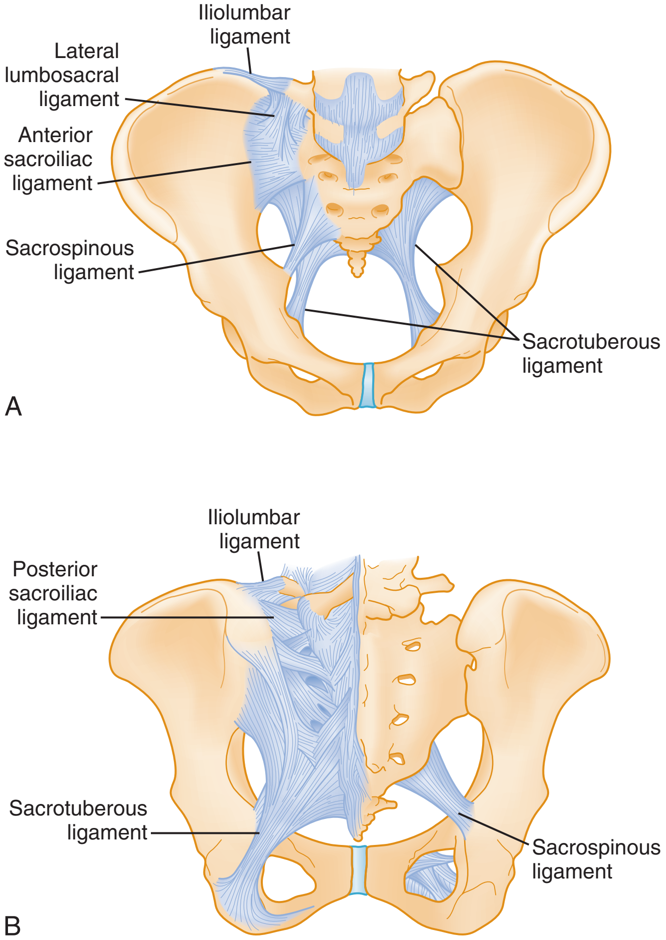

Figure 55-2. **A,** Anteroposterior view of the pelvis indicates that the sacrospinous ligament is a triangular strong ligament lying anterior to the sacrotuberous ligament, which is a strong broad band extending from the lateral portion of the dorsum of the sacrum to the ischial tuberosity. **B,** The major posterior stabilizing structures of the pelvic ring, that is, the posterior tension band of the pelvis, include the iliolumbar ligament, posterior sacroiliac ligaments, sacrospinous ligaments, and sacrotuberous ligaments.

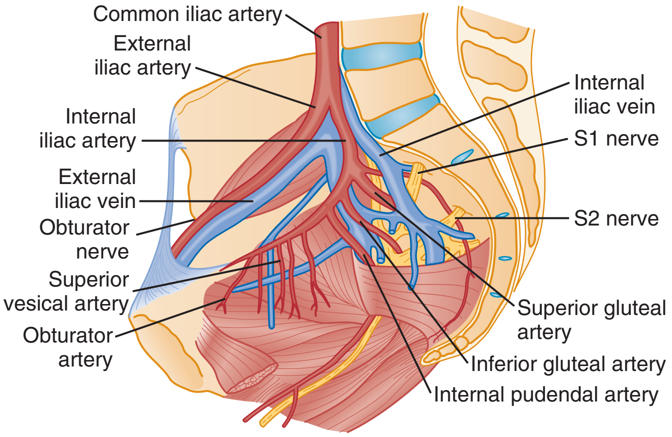

Figure 55-3. The internal iliac plexus of arteries and veins. (From Tile M: Fractures of the Pelvis and Acetabulum, 3rd ed. Philadelphia, Lippincott, Williams & Wilkins, 2003.)

The venous system also has many collateral branches and is without valves, allowing bidirectional flow. The veins are arranged in a plexus that adheres closely to the pelvic walls. Because these veins are thin-walled, they do not have the ability to constrict in response to damage. This anatomic arrangement of the arteries and veins accounts for the hemorrhage often seen with pelvic fractures.

Neurologic Anatomy

The cauda equina courses through the sacral spinal canal and exits through the sacral neural foramina to form the lumbar and sacral plexus. Injury to the posterior bony pelvis and sacrum may result in neurologic deficits in the lower extremities and autonomic dysfunction involving the bowel, bladder, and genitalia.

Pathophysiology and Key Patterns of Pelvic Fracture

Numerous classification schemes exist for pelvic fractures. Two widely used schemes for pelvic injury are presented here. The classification by Tile stresses the biomechanical stability of the pelvic ring[15] (Box 55-1). The Young-Burgess classification emphasizes the mechanisms of injury[16] (Box 55-2). From a practical viewpoint, it is highly useful to consider both of these elements in the assessment of a pelvic ring fracture. Within both classification systems exist numerous subtypes of injuries, the interobserver

www.ketabpezeshki.com 66485457-66963820

Box 55-1 Tile's Classification of Pelvic Fractures

Type A—Stable, posterior arch intact
Includes avulsion fractures, isolated iliac wing fracture, pubic rami fractures, minimally displaced ring fracture, transverse fractures of the sacrum or coccyx.
Type B—Partially stable, incomplete disruption of the posterior arch
Includes anteroposterior injuries (open book) and lateral compression injuries. May be unilateral or bilateral. These injuries are rotationally unstable but vertically stable.
Type C—Unstable, complete disruption of the posterior arch
Includes iliac, sacroiliac, and vertical sacral injuries that result from vertical shearing forces. May be unilateral or bilateral. These injuries are both rotationally and vertically unstable.

From Tile M: Fractures of the Pelvis and Acetabulum, 3rd ed. Philadelphia, Lippincott, Williams & Wilkins, 2003.

Box 55-2 Young-Burgess Classification of Pelvic Fractures

Anteroposterior Compression
I. Symphysis diastasis <2.5 cm
II. Symphysis diastasis >2.5 cm, sacrospinous and anterior SI ligament disruption, results in rotational instability
III. Symphysis diastasis >2.5 cm, with complete disruption of the anterior and posterior SI ligament, results in complete rotational and vertical instability

Lateral Compression
I. Sacral crush injury on ipsilateral side
II. Sacral crush injury with disruption of posterior SI ligaments; iliac wing fracture may be present (crescent fracture); rotationally unstable
III. Severe internal rotation of ipsilateral hemipelvis with external rotation of contralateral side ("windswept" pelvis), rotationally unstable

Vertical Shear
Vertical displacement of symphysis and sacroiliac joints resulting in complete rotational and vertical instability

Combined Mechanisms
Any combination of the above mechanisms

From Burgess AR, Eastridge BJ, Young JW, et al: Pelvic ring disruptions: Effective classification system and treatment protocols. J Trauma 30:848, 1990.
SI, sacroiliac.

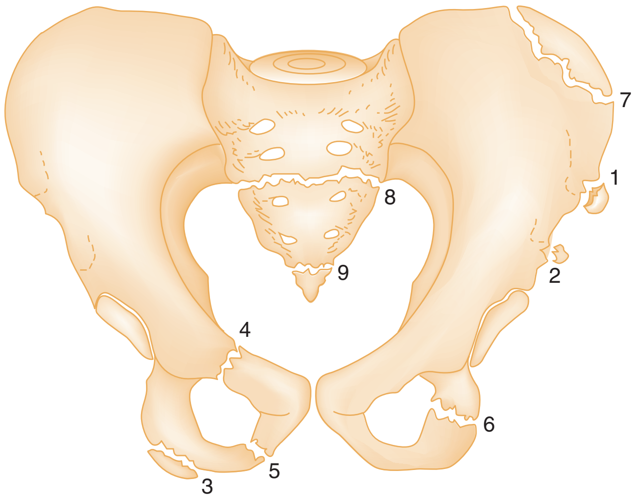

Figure 55-4. Fractures of individual pelvic bones. *(1)* Avulsion of anterosuperior iliac spine, *(2)* avulsion of anteroinferior iliac spine, *(3)* avulsion of ischial tuberosity, *(4)* fracture of superior pubic ramus, *(5)* fracture of inferior pubic ramus, *(6)* fracture of ischial ramus, *(7)* fracture of iliac wing, *(8)* transverse fracture of sacrum, *(9)* fracture of coccyx. (From Tile M: Fractures of the Pelvis and Acetabulum, 3rd ed. Philadelphia, Lippincott, Williams & Wilkins, 2003.)

reliability of which has been questioned.[17,18] For the emergency physician, a good understanding of both the underlying principles of pelvic stability and mechanisms of injury is far more important than a detailed knowledge of the numerous subtypes of injury that exist within the classification schemes. The broad distinction of mechanically stable from unstable fractures of the pelvic ring is clinically useful to bear in mind in assessing patients, as it has been demonstrated consistently over time that those with unstable injuries have higher mortality and greater transfusion requirements.[16,19,20]

Stable Injuries (Tile Type A)

Fractures of individual bones without involvement of the pelvic ring represent one third of all pelvic fractures. In general, most stable pelvic fractures heal well with rest and analgesic drugs for pain control (Fig. 55-4).[15]
